Where the intended service will involve contact with dilute sulfuric acid the resistance of the alloy can be improved by the addition of 2 to 3% Mo. Higher molybdenum content is sometimes specified for special conditions of corrosion, but such alloys are less resistant to corrosion in nitric acid than the molybdenum-free material.

Columbium and selenium are also used as special additions to the normal CF composition—columbium as a stabilizing element to avoid intergranular attack, and selenium to improve machinability.

Typical mechanical properties for CF alloys water quenched from about 2000 F are listed in Table IV.

Type CG. This alloy is nearly the same as the CF composition in corrosion resistance and mechanical properties. The nickel and chromium contents are higher than in the CF type, thereby allowing somewhat higher carbon content without loss of resistance to corrosion. CG alloys are made in low-carbon and medium-carbon grades and with molybdenum, columbium and selenium additions. Castings of this composition are heat treated by quenching from about 2000 F.

Type CH. The 25% Cr, 12% Ni alloy with less than 0.20% C is similar to the CE composition. It is used for specialized applications in the chemical and paper industries. The CH type is made in two carbon grades: 0.10%

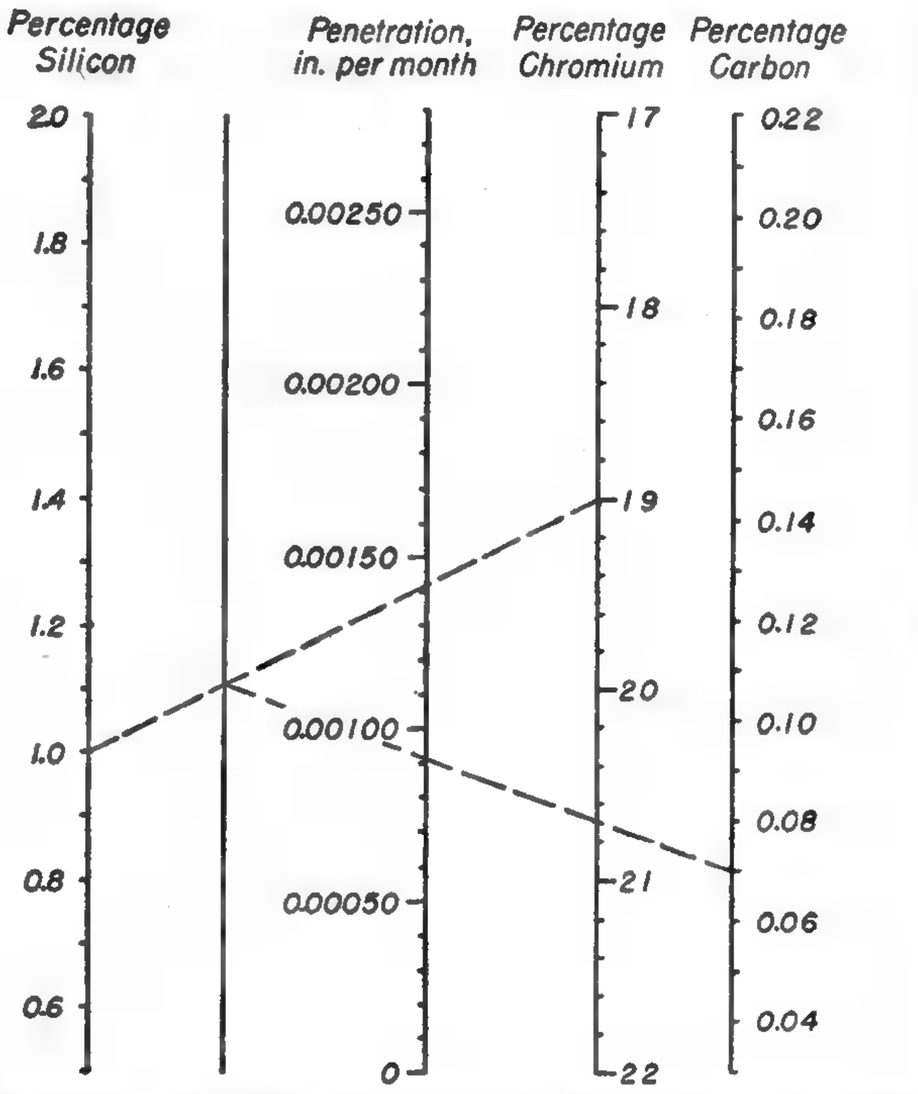

Fig. 9 Nomograph for determining rate of penetration in 65% boiling nitric acid for quench-annealed CF and CG type alloys (Reference 3)

and 0.20% C max. For resistance to reducing chemicals, molybdenum is added to the low-carbon type. Typical mechanical properties for alloys water quenched from 2000 F are shown in Table V.

Table V. Mechanical Properties of Type CH Alloys (25% Cr, 12% Ni)

Property	CH-10	CH-20	CH-10M[a]
Tensile strength, psi	82,000	88,000	90,000
Yield strength, psi	44,000	50,000	66,000
Elongation, per cent in 2 in.	38	38	15
Brinell hardness number	170	180	180

(a) Containing molybdenum

Type CK. This alloy is used extensively in the pulp and paper industry. It is similar to the CE and CH compositions, but has considerably higher nickel content. The CK type is sometimes made with a columbium addition to minimize the effect of carbide precipitation. Typical mechanical properties of an alloy quenched from 2000 F are as follows:

Tensile strength, psi	75,000
Yield strength, psi	45,000
Elongation, per cent in 2 in.	20
Brinell hardness number	180

Machinability characteristics of all the iron-chromium-nickel type alloys (chromium in excess of nickel) are about on ■ par with the quench-annealed CF type composition. The CE-30 type and the alloys that contain columbium are somewhat easier to machine; the alloys that contain selenium also have improved machinability; the CH type is slightly less machinable than the CF type.

All these alloys are readily weldable but, with the exception of the CE type (as previously discussed) and the stabilized compositions that contain columbium, all must be heat treated again after welding. It is advisable to preheat the molybdenum-containing CH type alloys at 600 to 1000 F before welding.

Iron-Nickel-Chromium Alloys. Alloys in which the nickel content exceeds the chromium content are made in the compositions listed in Table VI.

Table VI. Composition Limits of Iron-Nickel-Chromium Corrosion-Resistant Castings

ACI Type	Composition, percentage				
	Carbon	Manganese	Silicon	Chromium	Nickel
CM-25	0.25 max	1.50 max	2.00 max	8 to 11	19 to 22
CN-7	0.07 max	1.50 max	2.00 max	18 to 22	20 to 30
CT-7	0.07 max	1.50 max	2.00 max	13 to 17	34 to 37

Type CM-25. This composition is used in equipment for oil refineries and in special applications where dilute sulfuric acid is encountered. Typical mechanical properties are as follows:

Tensile strength, psi	71,000
Yield strength, psi	34,000
Elongation, per cent in 2 in.	38
Brinell hardness number	128

Types CN-7 and CT-7. These alloys are used for resistance to various concentrations of hot sulfuric acid and for specialized applications of severely corrosive nature. The compositions usually contain molybdenum and other alloying elements. Within the broad ranges of nickel and chromium are several proprietary, patented alloys. The iron-nickel-chromium alloys are machinable and weldable to about the same extent as the more widely used iron-chromium-nickel alloy types.

Influence of Composition on Resistance to Corrosion. Corrosion-resistant alloys may be exposed to five types of corrosive attack, namely: (1) *general attack,* in which the entire surface is corroded at an approximately uniform rate; (2) *intergranular attack,* in which corrosion proceeds along the grain boundaries, causing disintegration of the metal; (3) *contact corrosion,* in which the products of corrosion are concentrated at the point of contact of the alloy with another body, causing localized attack; (4) *pitting corrosion,* in which the general surface remains relatively unattacked, but severe corrosion occurs at some points; and (5) *erosion-corrosion,* in which erosive action continuously removes the passive film on the surface of the metal, causing active corrosion at a rate higher than ordinary, along the path of erosion.

In alloys of the CF and CG types, the influence of composition on the rates of corrosion caused by *general attack* has been studied at Battelle Memorial Institute for the Alloy Casting Institute, and certain definite relationships have been established. Through use of the Huey test (average rates of corrosion determined from specimens immersed in boiling 65% nitric acid for five 48-hr test periods) it has been shown that in this standardized environment, carbide-free, quench-annealed alloys of varying nickel, chromium, silicon, carbon and manganese contents, have corrosion rates directly related to the amounts of the elements present in the composition. Figure 8 shows the influence of each of the elements on the corrosion rate. Variations within the normal ranges of nickel, manganese and nitrogen contents have relatively little effect on the rate, but chromium, carbon and silicon have a marked influence on resistance to corrosion. The corrosion rate for a given composition depends on the actual analysis. However, the effect of each element remains the same, regardless of the amounts of the other elements present. The relationship of composition to corrosion rates for properly heat treated CF alloys in boiling 65% nitric acid, is summarized in the nomograph of Fig. 9.

Intergranular attack may be avoided in the CF and CG alloys by the two following methods: (1) by the addition of the stabilizing element columbium, or (2) by the formation of an austenite-ferrite structure obtained through the addition of molybdenum or through changes in the silicon and chromium contents. The addition of columbium to molybdenum-containing alloys of the normal CF and CG compositions has been found unsatisfactory for castings. If the addition of these two elements to the same alloy is desired, a special composition must be employed, containing amounts of nickel considerably higher than normal. In general, intergranular corrosion is of less concern in alloys that contain 25% Cr or more, than in the lower-chromium alloys.

Corrosion Testing. Accelerated corrosion tests, although useful for laboratory study of corrosion-resistant alloys, should not be considered valid criteria in determining the suitability of alloys for castings in service installations. It is virtually impossible to duplicate service conditions in any laboratory test; for this reason, experience in similar applications is a better guide for selection of compositions.

Casting Design. In this article no comments have been made concerning comparative serviceability of the different alloys, because such comparisons are more likely to be misleading than helpful. All the alloy compositions have individual peculiarities as far as foundry practice is concerned, and the experience of the foundryman should be relied on in determining casting designs.

Wrought Stainless Steels

By Owen K. Parmiter*

THE WROUGHT stainless steels in common use are of three principal types: austenitic, martensitic, and ferritic. Some of these steels are used extensively where strength or resistance to scaling at elevated temperatures is required; such grades are discussed in the article on "Wrought Heat-Resisting Alloys", page 562. The properties of corrosion-resistant steel castings are given in the article on page 549.

Austenitic Stainless Steels. The stainless steels that are austenitic (and not ferromagnetic) contain both chromium and nickel; as shown in Table I the total content of these elements is at least 23%; the minimum content of chromium is 16% and of nickel, 7%. Types 302, 303, 304 and 316 are probably the most extensively used alloys of this class. Austenitic stainless steels work harden readily. They are extremely shock-resistant and difficult to machine unless they contain sulfur or selenium. They can be hot worked readily, and can be cold worked when proper allowance is made for their rapid work hardening. These steels can be welded without difficulty and, if the welding operation is controlled properly, the resistance to corrosion is not impaired. These steels have the best high-temperature

* Metallurgical Engineer, Firth Sterling Steel & Carbide Corp., McKeesport, Pa.

Table I. Composition Limits of Austenitic Stainless Steels

AISI Type No.	Composition, percentage: Carbon	Chromium	Nickel	Other Elements	General Properties and Uses
301	0.08 to 0.20	16.0 to 18.0	6.00 to 8.00	Mn 2.00 max	A general-utility stainless steel, easily worked; for trim, household utensils, structural purposes
302	0.08 to 0.20	17.0 to 19.0	8.00 to 10.00	Mn 2.00 max	A readily fabricated stainless steel for decorative or corrosion-resistant use
302B	0.08 to 0.20	17.0 to 19.0	8.00 to 10.00	Si 2.00 to 3.00 Mn 2.00 max	Silicon added to increase resistance to scaling at high temperatures
303	0.15 max	17.0 to 19.0	8.00 to 10.00	P, S, Se 0.07 min Zr, Mo 0.60 max	A free-machining grade 18-8 stainless steel
304	0.08 max	18.0 to 20.0	8.00 to 11.00	Mn 2.00 max	A low-carbon 18-8 steel, weldable with less danger of intercrystalline corrosion
308	0.08 max	19.0 to 21.0	10.00 to 12.00	Mn 2.00 max	For use when corrosion resistance greater than that of 18-8 is needed
309	0.20 max	22.0 to 24.0	12.00 to 15.00	Mn 2.00 max	For use at elevated temperature, combining high scaling resistance and good strength
309S	0.08 max	22.0 to 24.0	12.00 to 15.00	Mn 2.00 max	Low carbon permits welded fabrication with a minimum of carbide precipitation
310	0.25 max	24.0 to 26.0	19.0 to 22.0	Mn 2.00 max	Similar to 25-12 stainless, with higher nickel content for greater stability at welding temperatures
316	0.10 max	16.0 to 18.0	10.0 to 14.0	Mo 2.00 to 3.00	Superior resistance to chemical corrosion
317	0.10 max	18.0 to 20.0	11.0 to 14.0	Mo 3.00 to 4.00	Higher alloy content than 316 for increased corrosion resistance
321	0.08 max	17.0 to 19.0	8.0 to 11.0	Ti min 5 times C	An 18-8 type, stabilized against intercrystalline corrosion at elevated temperatures
347	0.08 max	17.0 to 19.0	9.00 to 12.00	Cb 10 times C	A stabilized 18-8 steel for service at elevated temperatures

Table II. Composition Limits of Martensitic Stainless Steels

AISI Type No.	Composition, percentage: Carbon	Chromium	Nickel	Other Elements	General Properties and Uses
403	0.15 max	11.5 to 13.0	.....	.....	Widely used for forged turbine blades
410	0.15 max	11.5 to 13.5	.....	.....	A low-priced general-purpose heat treatable stainless steel
414	0.15 max	11.5 to 13.5	1.25 to 2.50	.....	For springs, knife blades, tempered rules
416	0.15 max	12.0 to 14.0	.....	P, S, Se 0.07 min Zr, Mo 0.60 max	A free-machining grade
420	more than 0.15	12.0 to 14.0	.....	.....	For cutlery, surgical instruments, valves, ball bearings, magnets
420F	more than 0.15	12.0 to 14.0	.....	P, S, Se 0.07 min Zr, Mo 0.60 max	A free-machining variation of 420
431	0.20 max	15.0 to 17.0	1.25 to 2.50	.....	For high mechanical properties
440A	0.60 to 0.75	16.0 to 18.0	.....	Mo 0.75 max	For instruments, cutlery, valves; high hardness obtainable in high-carbon grades
440B	0.75 to 0.95	16.0 to 18.0	.....	Mo 0.75 max	
440C	0.95 to 1.20	16.0 to 18.0	.....	Mo 0.75 max	
501	more than 0.10	4.00 to 6.00	.....	.....	Corrosion-resistant rather than stainless; good strength at elevated temperatures
502	0.10 max	4.00 to 6.00	.....	.....	Corrosion-resistant rather than stainless; good strength at elevated temperatures

strength and resistance to scaling of the stainless steels; however, they are subject to intercrystalline corrosion at temperatures between 800 and 1600 F unless the structure is "stabilized" to prevent the presence of carbide at or near the grain boundaries. The corrosion resistance of the austenitic stainless steels is usually better than that of the martensitic or ferritic steels.

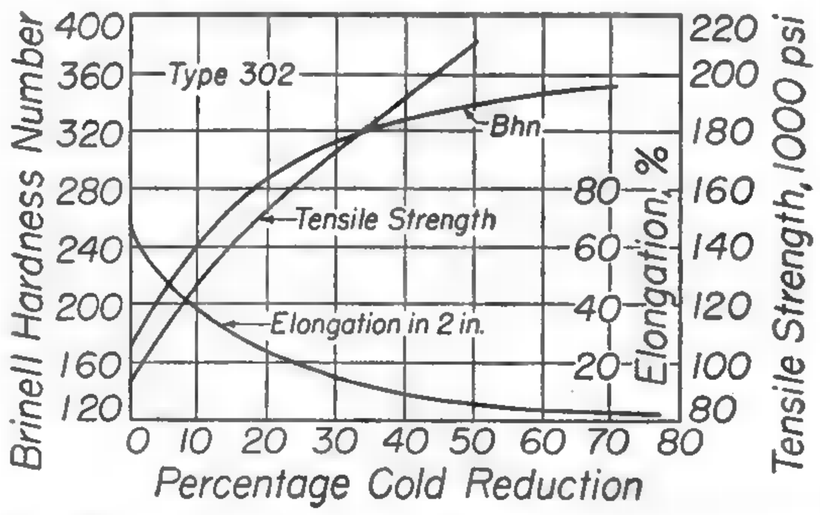

Fig. 1 Influence of cold work on a typical 18-8 stainless steel containing 0.11% C, 18.47% Cr, 8.20% Ni. Stainless steels of lower carbon content will work harden more rapidly; with carbon content higher than 0.11%, the rate of work hardening will be somewhat less than indicated.

Martensitic Stainless Steels. The steels that can be hardened by heat treatment are primarily straight chromium steels of the compositions shown in Table II. Types 410 and 416 are probably the most commonly used alloys of this class. The martensitic types of stainless steel are ferromagnetic; can be cold worked without difficulty, especially when the carbon content is low; show satisfactory resistance to weather, to water and to some chemicals; can be machined satisfactorily; have good toughness; and are easily forged or otherwise hot worked. The corrosion resistance is usually increased by hardening, but to obtain best resistance to corrosion it is important to quench from the recommended temperatures, especially for the high-carbon grades. The martensitic types of stainless steels

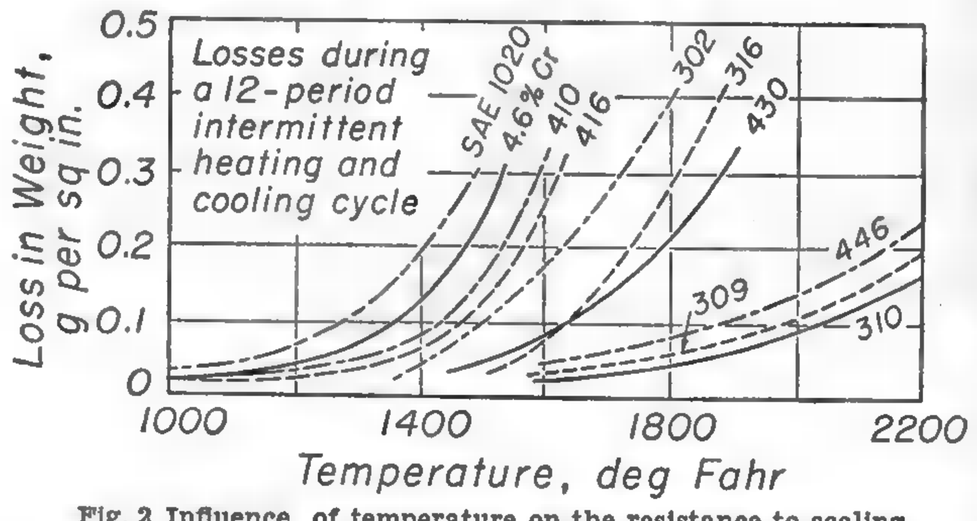

Fig. 2 Influence of temperature on the resistance to scaling of nine stainless steels and SAE 1020

tend to harden when cooled in air from above 1500 F; welds made by the electric-arc, resistance, or gas methods will consequently contain some martensite after cooling to atmospheric temperature. At temperatures below 1200 F the strength is greater than that of carbon steel.

Ferritic Stainless Steels. These alloys are chromium steels that are not hardenable by heat treatment (Table III). They can be cold worked or hot worked, are ferromagnetic, usually undergo excessive grain growth during prolonged exposure to elevated temperatures and may develop brittleness after electric-arc, resistance, or gas welding. These steels have lower strength at elevated temperatures than the martensitic type. However, resistance to scaling and to corrosion are generally better. Machinability

Table III. Composition Limits of Ferritic Stainless Steels

AISI Type No.	Composition, percentage: Carbon	Chromium	Nickel	Other Elements	General Properties and Uses
405	0.08 max	11.5 to 13.5	.....	Al 0.10 to 0.30	Nonhardening when air cooled from high temperatures
406	0.15 max	12.0 to 14.0	.....	Al 3.50 to 4.50	For electrical resistances; aluminum also reduces air hardening
430	0.12 max	14.0 to 18.0	.....	.....	An easily formed stainless alloy, much used for automobile trim and chemical equipment
430F	0.12 max	14.0 to 18.0	.....	P, S, Se 0.07 min Zr, Mo 0.60 max	A free-machining variety of 430
442	0.20 max	18.0 to 23.0	.....	.....	For high-temperature service when ease of fabrication is not required
443	0.20 max	18.0 to 23.0	.....	Cu 0.90 to 1.25	An easily worked steel of high corrosion resistance, for chemical equipment, and use at elevated temperatures.
446	0.35 max	23.0 to 27.0	.....	.....	High resistance to corrosion and scaling resistance up to 2150 F

Table VII. Some General Properties of Wrought Stainless Steels

Type	Magnetic Permeability Annealed	Electrical Resistivity, microhms/in.,[2] 70 F	Scaling Temperature, °F: Continuous Service	Scaling Temperature, °F: Intermittent Service	Welding Properties	Machining Properties	Drawing or Stamping
302	1.003	27.6	1600	1450	Very good; tough welds	Fair, tough	Very good
303	1.003	27.6	1600	1450	Fairly good. May crack; not recommended	Good, about 65% of screw stock	Fairly good
309	1.003	30.0	2000	1800	Good	Fair, tough	Good
310	1.001	30.5	2000	1900	Good	Fair, tough	Good
316	1.003	28.5	1650	1500	Very good	Fair, tough	Good
321	1.003	28.0	1600	1450	Very good	Fair, tough	Good
347	1.001	28.0	1600	1450	Very good	Fair, tough	Good
SAE 1020	Ferromagnetic	4.32	800	1000	Good	Good	Good
410	Ferromagnetic	22.5	1250	1400	Fair. Small welds can be annealed.	Fair	Fair
416	Ferromagnetic	22.7	1250	1400	Poor. Small welds likely to crack; not recommended	Good, about 80% of screw stock	Poor
420	Ferromagnetic	23.0	....	....	Fair. Brittle welds can be annealed.	Fair	Poor
430	Ferromagnetic	23.5	1500	1600	Fair. Brittle welds have slight response to anneal.	Fair	Good
440	Ferromagnetic	24.0	....	....	Not recommended generally	Fair	Poor
446	Ferromagnetic	26.5	1900	2000	Fair. Brittle welds have slight response to anneal.	Fair	Poor

is good and can be improved by adding sulfur or selenium. There is no tendency toward intercrystalline corrosion.

Physical and Mechanical Properties. The physical and mechanical properties of typical stainless steels of the three principal types are listed in Tables IV, V, VI, and VII. Figure 1 shows the influence of cold work on a type 302 (18-8) stainless steel.

Heat Treatment. Forging, annealing, hardening and tempering treatments are given in Table VIII. During heat treatment, carburizing conditions should be avoided because an increase in the carbon content of the surface of the steel will lower the resistance to corrosion. For stress relieving after hardening, the martensitic steels may be heated to temperatures between 300 and 700 F. The austenitic alloys are annealed in order to soften after cold working or to dissolve carbides.

Mechanical Properties at Elevated Temperatures. The tensile strength, rupture strength, creep strength and fatigue strength of typical stainless steels at elevated temperatures are given in the article on "Wrought Heat-Resisting Alloys", page 562.

Mechanical Properties at Low Temperatures. See the article on "The Properties of Metals at Low Temperatures", page 204.

Resistance to Scaling. The resistance of several grades to scaling is given in Fig. 2 and Table VII. The article on "Wrought Heat-Resisting Alloys" lists the normal operating ranges of temperature for 14 of the standard alloys.

Corrosion Resistance. The article on "Resistance of Stainless Steels to Corrosion", discusses the effect of various corrosive environments, of cold work, heat treatment and microstructure on the corrosion properties of stainless steel. *See also* "Stress Corrosion of Metals", page 227.

(a) Quench in water unless otherwise noted. FC = furnace cool; AC = air cool

(b) WQ = water quench; OQ = oil quench

(c) Except by cold working. The free-machining types (303, 416, 430F) are designed for machining applications and are not recommended for cold shaping or hot forging operations that require severe deformations.

The Resistance of Wrought Stainless Steels to Corrosion

By W. O. Binder*

STAINLESS steels are corrosion-resistant materials that rely mainly on surface passivity for resistance to attack. The use of these steels is governed by the oxidizing characteristics of the environment. For strongly oxidizing conditions, stainless steels are superior to the more noble metals and alloys.

The stainless steels may be grouped according to chemical composition and response to heat treatment, as follows: (a) martensitic steels, containing 11.5 to 18% Cr, (b) ferritic nonhardenable steels, containing 15 to 30% Cr, and (c) austenitic steels, containing 16 to 26% Cr and 6 to 22% Ni. All these steels are produced in the form of castings and wrought materials, which have been used extensively in industry because of their strength, toughness, good fabricating characteristics, and resistance to heat as well as to chemical and atmospheric corrosion.

The martensitic steels have chromium (11.5 to 18%) as the principal alloying element, and may contain from 0.08 to 1.10% C. The steels in this group respond to heat treatment in much the same manner as plain carbon and low-alloy steels. Further details in connection with the heat treatment may be found in the article on page 553 in this Handbook. Because of relatively low chromium content, the martensitic steels are used principally for resistance to atmospheric oxidation and to mildly corrosive chemicals. One of the earliest and best known applications of this type of steel is in cutlery.

Because they contain more chromium than the martensitic steels, the steels in group *b* have a stable ferritic structure, and they do not harden to any appreciable extent when quenched from high temperatures. The nonhardenable steels are extremely resistant to oxidation and to strongly oxidizing solutions. In addition to applications in chemical plants, these steels are widely employed in the form ot sheet and strip for structural purposes.

The addition of 6 to 22% Ni to low-carbon steels that contain 16 to 25% Cr, retards the transformation of austenite to ferrite so that austenite is retained at atmospheric temperatures when the steels are cooled from elevated temperatures. As indicated in the articles on cast and wrought stainless steels, the austenitic steels have greater strength at elevated temperatures than the plain chromium steels; they cannot be hardened except by cold work; and they are adaptable to cold forming operations. Because of the ease of fabricating them by welding and because they resist corrision in various mediums, the austenitic steels have been used more extensively than any plain chromium steel.

Nature of Passivity in Stainless Steels.[1-6] It is believed, although not by all investigators, that the resistance to corrosion of the stainless steels results from the presence of a thin oxide or hydrate film on the surface of the metal, which is stabilized by chromium and protects the metal from attack. The film is considered insoluble, nonporous and self-healing. If broken, the film will repair itself when re-exposed to an oxidizing agent.

Investigators generally concede that passivation is not a constant state and that it exists only in certain environments or under certain conditions. In some instances, the range over which these steels exhibit passivity is relatively broad, but in others the range is narrow and passivity may be destroyed by slight changes in conditions. Under circumstances favorable to passivity, the stainless steels have a solution potential between the potentials of copper and silver. When passivity is destroyed, the potential is equal to that of ordinary iron. Passivity has a greater influence on the resistance to corrosion of the stainless steels than on the resistance of any other metal. For this reason the metal and environment factors affecting passivity will be discussed next.

Effect of Composition on Resistance to Corrosion.* The chromium steels derive their remarkable resistance to corrosion from the presence of chromium. Although additions of 1 to 12% Cr to steel enhance progressively the resistance to oxidation at elevated temperatures and to rusting in the atmosphere, the resistance to corrosion of these steels is ordinarily insufficient for successful chemical service until the chromium content reaches about 12%. The application of the chromium steels in the chemical industry is chiefly for resistance to oxidizing conditions. The data in Table I illustrate the effectiveness of chromium in developing passivity, and show that the steels become more resistant to oxidizing conditions as the chromium content is increased. The rate at which the steels develop passivity depends on their chromium content; steels that contain more than about 20% Cr become passive in the atmosphere without developing even a slight film of rust.

Table I. Influence of Chromium Content on the Resistance of Low-Carbon Steel to Boiling 65% Nitric Acid

Chromium, percentage	Average Rate of Corrosion, inches penetration per month
4.5	12.900
8.0	0.144
12.0	0.010
18.0	0.0025
25.0	0.00063

Silicon and aluminum further improve the resistance of the chromium steels to direct oxidation at elevated temperatures. Silicon in excess of the percentage required for deoxidizing the steels, reduces their resistance to hot concentrated solutions of nitric acid. In commercial grades of stainless steel, the use of aluminum is restricted to the 12% Cr steel (types 405 and 406†). Aluminum is employed in these steels to prevent air-hardening and to increase electrical resistivity.

The presence of nickel in the high-chromium steels decreases attack by nonoxidizing corrosives. Nickel increases somewhat the tendency of the chromium steels to become passive, but in strongly oxidizing conditions, nickel adds little to the passivity of steels that contain more than about 22% Cr.

Manganese has a beneficial effect on the hot workability of these steels, without reducing their resistance to corrosion. Manganese has been used to replace all or part of the nickel in the austenitic chromium steels,[7] but the chromium-manganese and chromium-manganese-nickel steels are less resistant than the fully austenitic steels that contain 18% Cr, 8% Ni.

The presence of molybdenum in the chromium steels and the austenitic 18% Cr — 8% Ni steels (type 316) improves their resistance to sulfuric, sulfurous and organic acids, halogen salts, and sea water. Additions of molybdenum strengthen the passive film under conditions in which it is likely to fail, but such additions lessen the resistance of the steels to corrosion in strongly oxidizing environments, if the amount of molybdenum present exceeds 3%. The action of molybdenum produces increased nobility as well as passivity. The addition of molybdenum greatly improves the resistance to pitting of the 18% Cr — 8% Ni steels. This type of corrosion will develop under foreign deposits that prevent access of oxygen to the surface of the steel. Pitting may also occur in environments that are oxidizing and free of foreign deposits. The mechanism by which steels corrode after a pit has formed has been described by Uhlig.[8]

Effect of Heat Treatment on Resistance to Corrosion.‡ The changes in microstructure produced by different heat treatments have considerable influence on the resistance to corrosion of the stainless steels. These steels exhibit greater resistance when carbon is completely dissolved, producing a homogeneous single-phase structure, than when the carbon is partially or completely divorced from solid solution.

* Metallurgist, Union Carbide and Carbon Research Laboratories, Inc., Niagara Falls, N. Y.

* For data concerning the effect of composition on the resistance of stainless steel castings to corrosion, see page 549.

† AISI type numbers and compositions of stainless steels are listed on pages 554 and 555.

‡ *See also* the article "Corrosion-Resistant Castings", page 549.

The martensitic steels must be properly heat treated to exhibit good resistance to corrosion, and although normally they show maximum resistance in the fully hardened condition, relief of quenching stresses, coupled with greatly improved ductility and toughness, may be obtained by tempering these steels at temperatures of 400 C (750 F) or less without seriously reducing their resistance to corrosion. However, tempering between 400 and 600 C (750 and 1110 F) should be avoided, particularly when the carbon content is high, since this range of temperature imparts low toughness as well as low resistance to corrosion.[9] Tempering temperatures higher than 600 C (1110 F) coagulate the precipitated carbides and offset the detrimental influence of the carbides on resistance to corrosion. Although in low-carbon ferritic nonhardenable chromium steels and in low-carbon steels that contain 12 to 14% Cr, the general resistance to corrosion is not affected noticeably by any form of heat treatment, it is advisable to anneal the nonhardenable steels after welding, in order to obtain maximum resistance to corrosion and to obtain ductility in the heat-affected zones adjacent to the weld.

When austenitic chromium-nickel steels are properly heat treated, they exhibit a wide range of passivity in corrosive solutions. These steels resist corrosion most effectively when they are heated to temperatures within the range from 1050 to 1100 C (1920 to 2010 F) and cooled rapidly, because this heat treatment produces a homogeneous austenitic structure. Rapid cooling from the heat treating temperature is essential in order to keep the carbides in solution. Very small parts may be air-cooled but larger parts must be water-quenched. These steels, however, are subject to severe attack at the grain boundaries by even relatively mild corrosive mediums after exposure to temperatures in the range from 400 to 900 C (750 to 1650 F). This attack is known as "intergranular corrosion". The cause of intergranular attack has been the subject of considerable research. Some investigators believe that this kind of attack results from precipitation of chromium carbide and consequent depletion of chromium in the area adjacent to the grain boundaries. Decreasing carbon content decreases susceptibility of the steel to intergranular attack.[10,12]

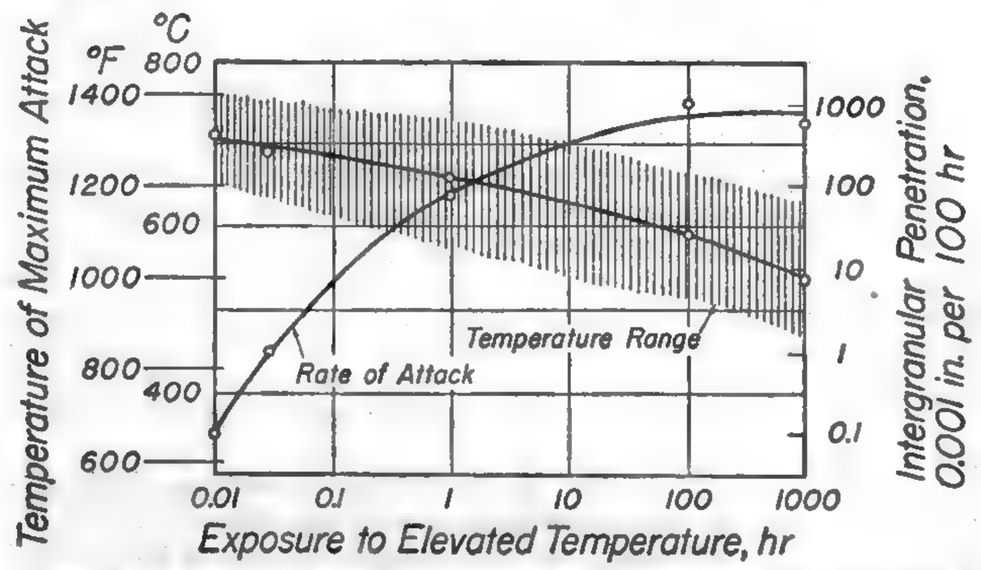

Fig. 1 Effect of time and temperature on the maximum sensitivity to intergranular attack of low-carbon steel containing 18% Cr, 8% Ni[12]

Besides carbon, the important factors are time, temperature and corrodent. The data shown in Fig. 1[12] illustrate the influence of time and temperature on sensitivity to intergranular attack. It should be emphasized that the precipitation of carbides at the grain boundaries may take place very rapidly. For example, after welding, the metal adjacent to the weld is subject to intergranular attack, whereas the weld metal itself and the base metal outside the heat-affected zone are virtually free from attack. The intergranular weakness may be removed by annealing the steel properly or may be avoided by using stabilized compositions (types 321 and 347).

The desire to use welded equipment of any size and to avoid inconvenience, distortion, and residual stresses caused by heat treatment and rapid cooling, led to the development of austenitic steels free from intergranular susceptibility.[11,13,14,21,25] The loss of resistance to corrosion because of carbide precipitation at grain boundaries, is eliminated by adding small amounts of titanium (type 321) or columbium (type 347). For complete immunity, the titanium content must be at least four to six times the carbon content; the columbium content must be eight to ten times the carbon content. Precipitation of carbide, detrimental to corrosion resistance, does not occur in the stabilized steels that contain 18% Cr, 8% Ni, when they are welded or stress-relieved. The steels that contain columbium (type 347) are suitable for welding rods, since nearly all the columbium in the rod is transferred to the weld.

As with other metals and alloys, the stainless steels sometimes show lower resistance to corrosion after cold work. This effect is rather specific and depends on the composition of the steel, the extent and uniformity of cold work, and particularly on the nature of the environment. For example, local cold work has a greater effect on the corrosion resistance of the steel than uniform cold work. In general, the greater the resistance to corrosion of the steel, the less likely that the steel will be attacked when it is cold worked locally.

Effect of Surface Condition. The stainless steels usually operate under severely corrosive conditions. To insure satisfactory service life the surface condition of the steel must be given careful attention, because smooth surfaces, freedom from defects and from all traces of scale, oil, and other foreign material, reduce the probability of corrosion. Generally the smoother the surface, the greater the resistance to corrosion. Oil and grease can be removed by either hydrocarbon solvents or alkaline cleaners, but care must be taken to remove these cleaners before heat treating the steels. Surface contamination may be caused by machining, shearing and drawing operations. Small particles of metals from the tools become embedded in the steel surface and, unless removed, may cause corrosion. These particles are removed best by immersing the surface in a solution containing approximately 20% nitric acid heated to a temperature between 50 and 60 C (122 and 140 F). This treatment also hastens the development of passivity.

Environment Factors Affecting Resistance to Corrosion. The important factors concerned with the corrosive environment are oxidizing characteristics, acidity, velocity and temperature.

Stainless steels are normally passive but, when exposed to corrosive solutions that are nonoxidizing, these steels become active. It is necessary, then, that oxidizers be present in solution to maintain passivity. The oxidizing agent producing passivity should be replenished constantly. Localized corrosion frequently results from depletion of the oxidizing agent. Pitting beneath a barnacle, in sea water, is a typical example of localized corrosion from depletion of oxygen.

In reducing or weakly oxidizing conditions, the resistance of stainless steels in dilute acids is increased by reducing the concentration of the acid. Because of decreased ionization, the corrosion rate of the steels may be less in concentrated acid than in dilute, when other factors are the same—for example, temperature. In highly concentrated acid—for example, in fuming sulfuric acid—corrosion is more severe because of changes in the chemical behavior of the acid itself; the rate of corrosion rises rapidly also with increasing temperature.

An increase in velocity of the corrosive solution increases the rate at which the oxidizing agent is brought in contact with the steel and, hence, does not normally reduce the resistance to corrosion of stainless steels unless the increased velocity is accompanied by abrasion. The effect of abrasion is to inhibit the formation of a passive film.

The rate of corrosion increases with rising temperatures, as a result of increased ionization, rate of diffusion, and mobility of the reactants. In weakly oxidizing conditions, a rise in temperature may increase the rate of corrosion by decreasing the amount of oxygen dissolved in the solution.

The above statements indicate the reason for the complex behavior of the stainless steels under corrosive conditions. The characteristics of both the steel and the corrosive environment must be fully recognized in order to apply these steels successfully to specific purposes. Since ordinarily not all the facts are known, it is frequently necessary to test the steels under operating conditions before any accurate selection can be made.

Galvanic and Concentration-Cell Corrosion. The factors influencing galvanic corrosion include conductivity of the

circuit, potential between anode and cathode, polarization, relative areas of cathode and anode, geometrical relationship between dissimilar metal surfaces, and contact between metals. Of these, the influence of relative areas of anodic and cathodic surfaces has the most pronounced effect on the degree of damage produced by galvanic action, since a small anode and a large cathode result in an increase in current density at the anode with a great consequent increase in the rate of corrosion. Thus, small differences in potential under these conditions may produce extensive corrosion because of increased current density in the anodic areas.

As shown in Table II,[15] the stainless steels will form galvanic couples when used in contact with other metals in the presence of an electrolyte. If the solution produces an active condition, metals like copper and bronze will accelerate the corrosion of stainless steel, particularly if the area of steel is small in comparison with the area of copper or bronze; but when the steels are passive, they are extremely stable in contact with these metals. In the passive condition the stainless steels are strongly cathodic; hence they will damage other metals, such as carbon steel, cast iron, and aluminum alloy, especially when the area of stainless steel is large in comparison with the other metal in the couple.

Table II. Galvanic Series of Metals and Alloys

Corroded end (anodic, or least noble)	
Magnesium	Hastelloy A
Magnesium alloys	Hastelloy B
Zinc	Brasses
Aluminum 2 S	Copper

18% Cr — 8% Ni — 3% Mo steel (active)	18% Cr — 8% Ni steel (passive)
Hastelloy C	18% Cr — 8% Ni — 3% Mo steel (passive)
Lead-tin solders	Silver
Lead	Graphite
Tin	Gold
Nickel (active)	Platinum
Inconel (active)	
	Protected end (cathodic, or most noble)

The type of corrosion associated with surface crevices, scale, and other surface deposits, is known as "concentration-cell corrosion". The types of cells most frequently encountered in the stainless steels are the oxygen and active: passive cells.[16] Oxygen cells will develop into active: passive cells when the re-establishment of passivity in the anodic area becomes impossible. Because of the large areas of passive metal that normally surround the anodic areas, the active:passive cells are extremely energetic, since the surrounding oxygen serves as a depolarizer by reacting with the hydrogen from the reaction. Solutions that contain chlorides are most active in promoting these cells, and severe pitting may develop from their action.

In order to prevent these cells from forming, cracks and crevices should be avoided in equipment that must resist corrosion. Concentration-cell corrosion is particularly troublesome at joints made with gaskets, so tight dry joints are essential for optimum service.

Effect of Stress.[17–20,22,29–32]* Stress-corrosion failures in stainless steels have been reported in solutions that contain chlorides, but the occasions of such failures have been relatively few, and the residual stresses have undoubtedly been high. Solutions of magnesium, zinc or lithium chlorides, and moist ethyl chloride in combination with a high stress, cause stress-corrosion cracking. Of these, a boiling concentrated solution of magnesium chloride is the most corrosive and will cause the austenitic steels to fail in short periods of time when the applied stress is near the yield strength of the steel. The corrosive environments causing stress-corrosion cracking, which have been encountered in the chemical industry, are rather specific and are limited to certain chloride solutions.

* *See also* the article "Stress Corrosion of Metals", page 227.

The 18% Cr — 8% Ni steel, having a tensile strength as high as 200,000 psi, has been used extensively for lightweight structures with no failures from stress-corrosion cracking, although exposed to all kinds of atmospheric conditions. Cold drawn articles made of this steel may crack as a result of high residual stresses introduced during fabrication. Such cracking does not require the presence of a corrosive atmosphere or solution and can be avoided by thermal stress-relieving of the metal after drawing. Optimum deep-drawing conditions are obtained with a steel containing 18% Cr and 10 to 12% Ni, which work hardens at a slow rate.

Corrosive Effects of Various Mediums.[6,7,9,26] Since the corrosion resistance of a material depends largely on the

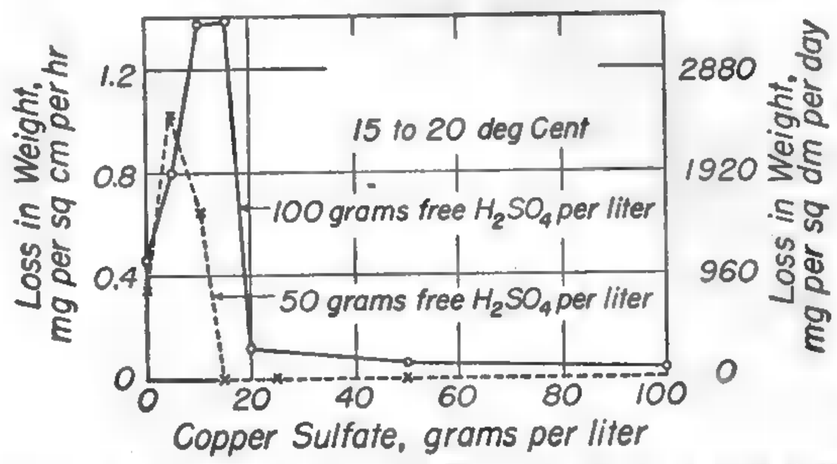

Fig. 2 Effect of copper sulfate on the corrosion of 12 to 14% Cr steel in sulfuric acid at 15 to 20 C[4]

nature of the corrosive condition, only broad general statements can be made; therefore the information given in this section should be used only as a preliminary guide. Whenever possible, specific tests or consultation with the manufacturer are advisable.

The resistance to corrosion of the stainless steels in acid solutions depends greatly on the oxidizing capacity of the solution. These steels are extremely resistant to acids, such as nitric acid, that have a high hydrogen-ion concentration and are strongly oxidizing in character. The presence of oxidizers like ferric and cupric sulfates in acid solutions permits the stainless steels to resist dilute

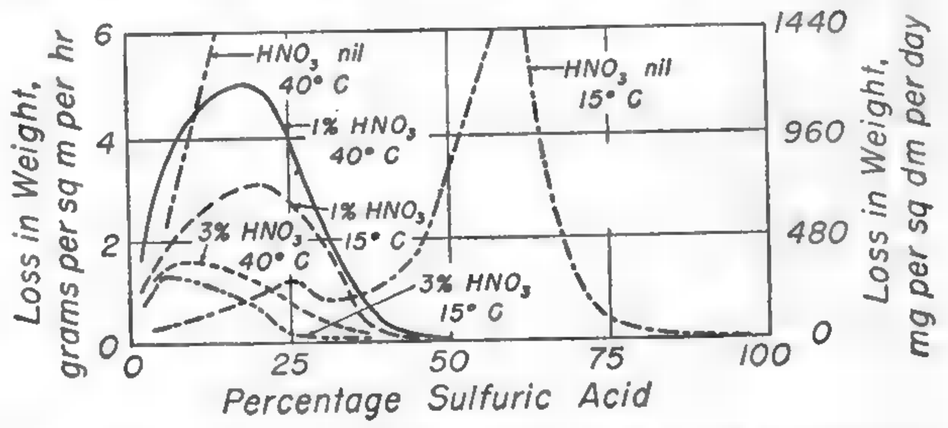

Fig. 3 Effect of a small addition of nitric acid on the corrosion of 15% Cr — 11% Ni steel in sulfuric acid[4]

acid solutions that exhibit high acidity and relatively low oxidizing power. These salts are more favorable to passivity than dissolved oxygen. Hydrochloric acid differs somewhat from the other acids in its action on the stainless steels, and it is difficult to render them passive in this acid. An increase in temperature increases the corrosion rate of the stainless steels in acids, particularly when the effect of raising temperature is to alter the oxidizing capacity of the solution.

Since the stainless steels that contain more than 16% Cr resist nitric acid solutions satisfactorily under most conditions of concentration and temperature, steels of this composition are used widely in equipment for resisting nitric acid. Typical corrosion rates of the stainless steels in boiling 65% nitric acid solution are given in Table III to illustrate the degree of passivity of these steels in a strongly oxidizing acid.

Sulfuric acid solutions, as already indicated, may or may not attack the stainless steels, depending on the concentration, temperature and oxidizing capacity of the

solution. When air or strong oxidizers are present, like nitric acid or cupric sulfate, the stainless steels exhibit a high degree of passivity (Fig. 2 and 3).

Cold concentrated sulfuric acid does not corrode the stainless steels, because of its greater oxidizing power and lower degree of ionization than cold dilute sulfuric acid solution; but hot concentrated solutions attack stainless steels. Molybdenum greatly improves the resistance of the 18% Cr — 8% Ni steels to sulfuric acid solutions, and considerable quantities of type 316 stainless steel are used in the textile industry, in which sulfuric acid solutions of various concentrations are employed.

						3	0.00060

(a) The duration of each period was 48 hr.

Provided their chromium content exceeds 12 to 15%, the stainless steels resist attack by pure sulfurous acids. The austenitic stainless steels are subject to intergranular attack in sulfurous acid solutions after welding, unless they are properly heat treated or fully stabilized. Large amounts of 18% Cr — 8% Ni steel—particularly steels containing molybdenum (type 316)—are used in the paper industry to resist the impure sulfurous acid solutions of the sulfite digesters.

The austenitic stainless steels are passive in all concentrations of acetic acid at temperatures as high as the boiling point. In hot acid, the resistance to corrosion of the 18% Cr — 8% Ni steels is improved by the addition of molybdenum, as shown in Table IV.

Under many conditions too numerous to mention specifically in this article, the stainless steels resist satisfactorily solutions of phosphoric acid, chromic acid, hydrogen sulfide and many organic acids. The degree of passivity in these acids is governed by the factors of concentration, temperature, and alloy content of the steel. Nickel and molybdenum help to enhance passivity, whereas increasing the temperature of the solution decreases passivity.

The stainless steels have been found satisfactory for handling weak and strong alkaline solutions at both room and elevated temperatures; for example, they are completely resistant to ammonia solutions.

Salt solutions usually contain sufficient amounts of dissolved oxygen to maintain passivity, and ordinarily they do not corrode the stainless steels. When acid chloride salts are present, however, attack may occur because the protective film is susceptible to penetration by the acid chloride solutions resulting from the hydrolysis of these salts. Oxidizing acid chloride salts are extremely corrosive; for instance, chlorides of copper, chromium, iron, tin, and mercury. Nonchloride oxidizing acid salts, such as dichromates, chromates, nitrates, and persulfates, do not attack the stainless steels. Oxidizing alkaline chloride salts liberate free chlorine as well as the chloride; hence in concentrated form they are corrosive, but in dilute form they are much less corrosive. The attack by dilute solutions is generally localized in the form of pits. Molybdenum additions increase the resistance of the 18% Cr — 8% Ni steels in salt solutions. Oxidizing alkaline solutions, such as solutions of sodium peroxide, are effectively resisted by the stainless steels, particularly the austenitic steels that contain 18% Cr, 8% Ni, with or without molybdenum. Because the austenitic stainless steels do not catalyze excessively the decomposition of peroxide solutions, they are used successfully in peroxide bleaching equipment.

Table IV

Results of Tests in Condensate of Boiling Acetic Acid

Steel	Corrosion Rate, inch penetration per month 80% acid	Glacial acid
304	0.0310 to 0.0378	0.0060 to 0.0088
347	0.0208 to 0.0230	0.0046 to 0.0056
316	0.00016 to 0.00028	0.00026 to 0.00030
309	0.00845 to 0.0103	0.0024 to 0.0051
310	0.00615 to 0.0074	0.00282 to 0.00305

Under some conditions, the steels are subject to pitting in dilute solutions of neutral salts. External conditions, such as adhering deposits, heat effects from welding, and surface imperfections, are troublesome because they greatly influence the attack. Continued exposure to sea water, as shown in Table V, may cause plain chromium steels, 18% Cr — 8% Ni steel, and other austenitic steels to pit, although general corrosion of the steel is virtually nil. The addition of molybdenum increases the resistance of these steels to pitting. The steels resist the action of sea water if oxygen is available to the metal surface.

Corrosion rates of the stainless steels in contact with food products are usually negligibly low, as shown in Table VI. In boiling fruit juices, which are acid in nature, the behavior of stainless steels is unlike that of the same steels when exposed to the pure forms of the organic acids, since the concentration of acids in fruit juices is low. For resisting excessively acid fruits, austenitic stainless steels of higher alloy content are preferred. For all practical purposes the stainless steels resist natural fresh waters, mine waters, boiler waters, and high-pressure steam at elevated temperatures. The austenitic stainless steels resist the action of a number of nonaqueous corroding liquids and gaseous corrodents, but are badly attacked by others. Data concerning several such mediums are listed in Tables VII and VIII.

C	Fairly resistant	1.0 to 3.0	0.0035 to 0.01

Moist chlorine and hydrochloric acid gases seriously attack the stainless steels at room temperature. The dry gases are not injurious to the austenitic steels at temperatures as high as 370 C (700 F).[27] When air is present, there is a possibility of more severe attack, and caution should be used in applying these limits. Sulfur dioxide is not active unless moist. The steels that contain 25% Cr, 12% Ni; 25% Cr, 20% Ni; and 18% Cr, 8% Ni, 2% Mo are more effective in resisting moist sulfur dioxide than is the 18% Cr — 8% Ni steel.

Stainless steels containing more than 18% Cr are extremely resistant to rural, industrial and marine atmospheres.[24,28] Wide use is made of these steels in architectural designs, for example in the Chrysler and Empire State buildings. It is necessary that the steel surface be free from scale and iron contamination; but if the surfaces are kept reasonably clean, they maintain their brightness indefinitely. The importance of cleaning frequently should be emphasized strongly, since dust and dirt act as contact corrodents, and may cause superficial rust spots.

Resistance to Corrosion at High Temperatures.* The chromium content influences the resistance of the stainless steels to atmospheres of oxidizing gas without sulfur, at elevated temperatures. A general view of the influence of chromium on the resistance of steel to oxidation may be gained from Fig. 4,[23] which indicates graphically that with ordinary steel, scaling begins at about 538 C (1000 F), and that additions of chromium increase progressively the resistance of steel to scaling. When 25% Cr is present, the steels resist scaling at temperatures as high as 1100 C (2010 F). The stainless steels most frequently used at high temperatures are those containing 25% Cr, 12% Ni (type 309), 25% Cr, 20% Ni (type 310), and 25 to 30% Cr (type 446), since these steels exhibit maximum resistance to oxidation. The steels that contain less chromium are also used at elevated temperatures, but the useful range is limited to temperatures below about 815 C (1500 F).

The presence of sulfur in hot oxidizing gases is not seriously harmful as long as the chromium content is high enough. When nickel is present in steel that is to be used in such an atmosphere, the chromium content should be at least 25%. Attack by sulfur is more severe in reducing gases than in oxidizing gases since sulfide corrosion products are less protective than oxides. However, the extent of the corrosive attack by hot sulfur compounds depends on the concentration of the sulfur compounds, the temperature, and the oxidizing power of the atmosphere. Practical observations indicate that the higher the chromium content of the steel, the more severe are the sulfur conditions that can be tolerated.

Under conditions that prevail in the manufacture of ammonia, the stainless steels show considerable resistance to attack, since the presence of chromium greatly retards the penetration of the hydrogen into steel.

The stainless steels carburize under reducing conditions, but their carburizing tendency decreases as the chromium content increases. Steels that contain 25% Cr with or without nickel, have been used in retorts for gas carburizing, and in seamless tubes for treating hydrocarbon gases at elevated temperatures. In steel used for treating hydrocarbon gases the nickel content is kept low in many instances to prevent unwanted catalytic reactions.

Austenitic steels that contain 18% Cr, 8% Ni as well as titanium or columbium (types 321 and 347) are extremely resistant to exhaust gases from internal combustion engines and are used widely in exhaust manifolds. Condensing flue gases usually contain small amounts of sulfuric acid, and the solution that condenses when the dew point is reached is extremely corrosive. However, the stainless steels that contain 18% Cr, 8% Ni, 2% Mo (type 316) have been found exceptionally resistant under such conditions and are used successfully in contact with flue gases.

Ordinarily the stainless steels are not used in contact with molten metals such as zinc, copper, brass, aluminum, and babbitt, because these metals attack the steels intergranularly. Fused compounds that may revert to caustic are also corrosive and, in general, the stainless steels are not suited for continuous exposure to molten chlorides or cyanides.

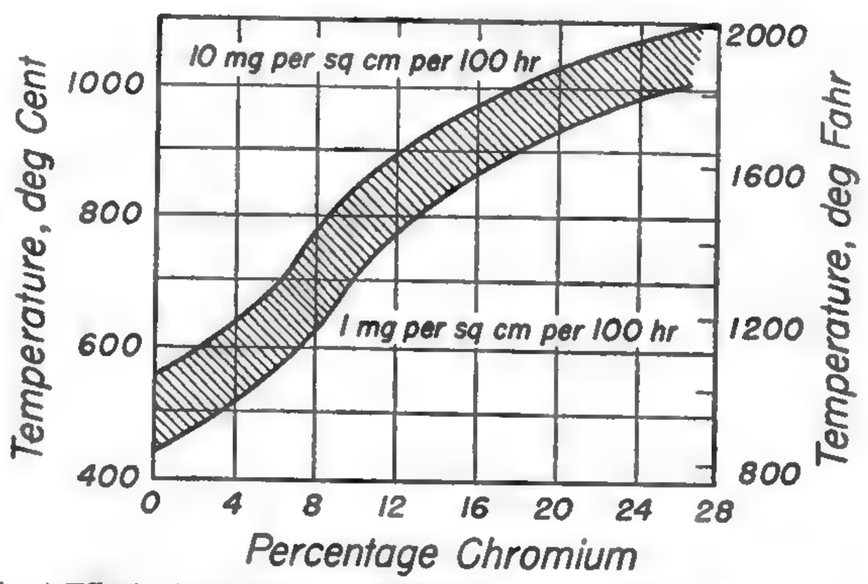

Fig. 4 Effect of increasing chromium content on the resistance of steel to oxidation[23]

Wrought Heat-Resisting Alloys

BY THE SUBCOMMITTEE ON WROUGHT HEAT-RESISTING ALLOYS*

THE USEFUL APPLICATION of wrought heat-resisting steels and alloys is becoming increasingly important in apparatus, parts and equipment required for high-pressure processes in chemical plants, for conversion of hydrocarbons, for generation of power, and in other structures or appliances that operate at elevated temperatures. Primary requirements include resistance to creep or rupture, resistance to oxidation and corrosion, sufficient ductility and workability for fabricating operations, and reasonable stability of structure so as to avoid detrimental changes in properties during exposure in service. These requirements are met in greater or lesser degree by the wrought heat-resisting steels now available to industry.

Recent developments in jet-propulsion engines, turbochargers and gas turbines, have been possible because of new wrought materials even stronger than those formerly available. These new materials are described briefly in following paragraphs. In addition, there are other, more specialized fields of application for high-temperature steels —for example, bolting steels and valve materials for internal-combustion engines. Because of their limited field of application in general construction, bolting materials will not be considered here. Although numerous low-alloy steels may properly be designated as high-temperature steels, this chapter defines heat-resisting steels as those containing 4% Cr or more, in accord with the present AISI commercial designation for such materials. In Table I are listed the compositions of the more important and most widely used wrought heat-resisting steels. These materials are available in all the usual commercial forms, such as plate, sheet,

(a) AISI Steel Products Manual, Section 24, Part 10

(b) Not all the compositions in this table conform strictly with those established for seamless tubing. Composition ranges for tubing are listed in AISI Steel Products Manual, Section 18, and in the following ASTM specifications: A 158, A 213, A268, A 269 and A 271.

(c) A modification of this type, known as 310B, contains 2.0 to 2.5% Si and is used to a considerable extent for carburizing boxes and furnace parts.

(d) This material is not listed as a standard AISI grade, but it has been used to some extent in wrought form.

strip, forgings, bars, rod, tubing and wire. Table II gives the nominal compositions of heat-resisting steels that have been used in making exhaust valves for internal-combustion engines.

General Requirements. Heat-resisting steels must meet two basic requirements: they should provide satisfactory resistance to oxidation or other chemical attack at the temperature and in the atmosphere of the intended service, and should provide sufficient strength to withstand loads that are either imposed by the structure itself or applied externally. The steel selected for use should meet these conditions without an excessive amount of stretch or flow.

All heat-resisting steels contain chromium in varying amounts, since their resistance to oxidation is obtained chiefly from chromium and ordinarily depends on the chromium content. Other metallic elements, such as silicon and aluminum, act similarly and are often added to chromium steels to obtain enhanced resistance.

NOTE. Alloys 1 to 9 are hardenable steels for use in automobiles and depend on chromium or chromium plus silicon or aluminum for resistance to oxidation. As the chromium content is increased, particularly with high silicon, it becomes necessary to increase the carbon content in order to maintain hardenability. The 19.5% Cr alloy 9 was devised for better resistance to gases that contain lead compounds. Alloys 10 to 19 are nonhardenable austenitic types designed for greater strength than the hardenable plain chromium types. Most of these are for high-duty and airplane engines.

Steels 20 and 21 are not hardenable by ordinary quenching. No. 20 is austenitic when quenched from a relatively high temperature and hardens during reheating. Alloy 21 ages to a hardness of about Rockwell C 40 while heating for a number of hours at 1400 F. This hardening is attributed to the formation of sigma phase. Alloy 21 has high resistance to attack by leaded gasolines.

Strength at elevated temperatures is obtained by the addition of metallic elements. At room temperature or at slightly elevated temperatures, carbon serves admirably, in conjunction with proper heat treatment, to increase the strength of steels; but where higher temperatures are involved, carbon is less effective. In most of the common constructional steels, the strength obtained by tempering is lowered drastically by prolonged heating at temperatures as low as 700 F. Additions of molybdenum, tungsten, or columbium are effective in increasing the strength of chromium steels at high temperature. However, at temperatures somewhat above 1000 F, no marked advantage is derived from these additions. To obtain increased strength within this higher temperature range it is necessary to use steels of an austenitic type. Nickel is added in appreciable amounts to accomplish this purpose. In some steels, manganese and nitrogen may be used in conjunction with nickel to promote formation of an austenitic structure. The strength of these austenitic steels may be increased further by addition of small amounts of molybdenum, tungsten, or columbium.

Many steels of both the ferritic and austenitic types are not structurally stable throughout the entire temperature range in which they may be used. Thus, when held in or slowly cooled through the range between 800 and 1000 F, ferritic 27% Cr steel loses in ductility and becomes somewhat less resistant to impact at room temperature because of the so-called "475 C brittleness". The formation of a constituent known as "sigma phase", which occurs at higher temperature (950 to about 1300 F) also has a serious embrittling effect. Heating to above 1200 F and cooling rapidly from that temperature alleviates the effect of the "475 C brittleness" and restores the original ductility; a temperature above 1500 F is required for the solution of sigma phase in the 27% Cr alloy. The plain chromium steels, down to about 15.5% Cr, lose some of their notch-impact toughness and ductility after prolonged heating within this range (800 to 1000 F); however, the original ductility is restored by heating above 1200 F, and then cooling rapidly.

Sigma phase, which is related to composition, may develop in austenitic steels during exposure to certain temperatures within the range from about 1100 to 1700 F. This transformation occurs most readily when the compositions are balanced so that high-temperature ferrite coexists with austenite in the annealed steel. Serious embrittling effects may occur in Types 309, 316 and 347, and sigma may also form in Types 309 and 310 even though the original structure is austenitic, especially if silicon is on the high side of the range. The precipitation of this phase may alter mechanical properties to a minor extent

Table III. Comparative Maximum Temperatures for Satisfactory Operation of Wrought Heat-Resisting Steels Without Excessive Scaling

No.	Material	Maximum Temperature,[a] deg Fahr

(a) Maximum temperature in oxidizing atmospheres without excessive scaling.

or to a marked extent, depending on the amount of sigma precipitated.

Since austenitic alloys that have been cooled rapidly from 1800 F and higher are supersaturated with carbon, chromium carbide is precipitated at the grain boundaries if the alloys are used within the range from about 900 to 1500 F, or if they are cooled slowly through this range. When these steels are tested at room temperature, lower ductility and higher tensile strength may result, after holding for extended periods of time in the range of carbide precipitation. However, short periods of time will not usually affect the mechanical properties to any measurable extent. In atmospheres that do not contain corrosive agents, the presence of the carbide phase has little effect on the performance of the steel. In the presence of corrosive gases, the carbide phase or areas at the grain boundaries may become susceptible to selective and rapid attack. The addition of appropriate amounts of columbium or titanium renders these alloys immune to attack of this nature. When the metal is in contact with hydrocarbon gases, carburization may influence the serviceability, especially at temperatures higher than about 1400 F. Even so, the austenitic alloys are used for the construction of carburizing furnaces and are often used for equipment to handle hydrocarbon fluids.

In order to meet the more exacting service requirements of gas turbines, a number of high-strength alloys have been developed. In some instances, less than 5% Fe is present. These new alloys have even greater strength at high temperature than the better known austenitic steels mentioned in the preceding paragraphs. These high-strength alloys contain enough chromium to ensure adequate resistance to oxidation, and have an iron and nickel or nickel and cobalt base, together with smaller amounts of columbium, molybdenum, tungsten or titanium to increase the strength at high temperature. Information concerning these special high-strength alloys is given in a later section of this article.

Table IV. Results of Scaling Test of Five Wrought Heat-Resisting Steels[a]

Test Conditions	Steels: 12 Cr	17 Cr	27 Cr	18-8	25-12
	Gain in Weight, mg per sq cm

50 hr 1800 F in hydrogen sulfide	1000.0	930.0	820.0	...	...

(a) More detailed information is included in Chapter 17 of "The Book of Stainless Steels", American Society for Metals, 1935

Resistance to Oxidation. Table III gives a suggested limit of operating temperature for ordinary use, which may require modification, depending on the severity of the oxidation rate as influenced by the type of atmosphere, amount of sulfur compounds present, or other factors that tend to increase the loss of metal. The scaling temperature or operating temperature limit given is based on arbitrary standards and indicates approximately the temperature at which, after prolonged heating in a strongly oxidizing atmosphere, a scale will form of sufficient thickness to cause flaking or spalling. The heat-resisting steels oxidize superficially at lower temperatures, forming a series of temper colors, until a thin, more or less adherent layer of scale is formed. This action proceeds very slowly until the scaling temperature is reached, whereupon progressive thickening of the scale layer, with spalling, causes much more rapid deterioration of the metal, thus reducing the service life or making mandatory the selection of a more highly alloyed material for economical and continued operation.

Modification of composition, by the addition of aluminum or silicon, affects the scaling temperature by changing the nature of the scale layer. A similar effect, also related to the nature of the scale, concerns the type of atmosphere in which the metal is tested. Table IV presents the results of scaling tests conducted in a highly oxidizing atmosphere and, for comparison, similar tests conducted in an atmosphere of hydrogen sulfide are cited also. At 1650 to 2010 F the chromium-rich oxide is refractory and

minimizes further chemical reaction, while the complex sulfides formed are liquid and promote interaction between the gas and metal phases. In reducing atmospheres where quantities of carbon monoxide are present, the scale formed is lower in chromium and therefore offers less protection. Furthermore, if carburization occurs, since carbon combines preferentially with chromium, the surface of the metal is depleted in effective chromium content—or, in other words, loses its "stainlessness" and forms scale more rapidly. During repeated heating and cooling, the ferritic stainless steels may scale less than austenitic steels because of their lower coefficient of thermal expansion. Numerous data concerning the resistance to oxidation of the heat-resisting steels under various conditions of exposure, are available in technical publications.

Mechanical Properties. Mechanical properties at ordinary temperature have no particular significance for heat-resisting steels, except as the data relate to fabrication of the part or to shock resistance at ambient temperature. In general, the plain chromium steels that contain more than about 15% Cr are notch-sensitive and are subject to grain growth during heating to high temperatures. Consequently, the plain chromium steels have a more limited field of application than the chromium-nickel austenitic steels. They also have less load-carrying ability when under stress at elevated temperatures.

In American practice, three types of tests are commonly employed to determine the high-temperature properties of metals; namely, short-time tension tests, rupture tests and creep tests (tensile or relaxation). Further information about the testing of metals at elevated temperature appears in the MECHANICAL TESTING section of this Handbook. The departure from room-temperature testing technique is necessitated by the fact that at temperatures higher than about 700 F a new phenomenon of flow becomes operative, which requires study on the basis of stress-strain-time factors at each temperature. The short-time tension test is similar in procedure to the ordinary tension test (*see* page 105) except that the specimen is enclosed in a furnace designed to ensure a uniform temperature over the specimen. The specimen is held at the designated testing temperature for a period of 30 min to one hour and is then pulled to fracture while still at temperature. Table V contains a compilation of data on tensile strength obtained by this type of test.

Short-time tensile, creep and rupture properties of metals are affected by the grain size, heat treatment, presence of cold work and the like, aside from the direct effect of composition. These factors are responsible for some of the divergencies in the data reported in various publications for given types of alloys. The wrought heat-resisting steels are usually applied in the annealed or softened condition. The data cited here concerning high-temperature properties, relate to annealed metal. The user of the data in this article should note that the specific heat treatment influences grain size; this may result in wide variation in high-temperature properties of the austenitic steels. In general, the coarse-grained steels have better resistance to creep or rupture than fine-grained steels but have poorer ability to elongate under stress.

Rupture Strength. The widely used stress-rupture test indicates the time required for fracture at a given temperature, under various constant loads. The data obtained by this method of testing are particularly useful for parts that have relatively short life in service, or where considerable uncertainty exists in regard to the temperature of the metal in service as, for example, in fired equipment. The stress-rupture test is similar to a creep test except that in the former, precise measurements of strain

(a) 0.5% Mo (b) 1.0% Mo

are not usually required and higher stresses are employed. A series of tests is made at each temperature under several loads and the time for fracture is noted. These data may then be plotted on logarithmic co-ordinates to determine the fracture time in 100, 1000, 10,000 or more hours, and from these graphs, service stresses or operating temperatures may be selected in accordance with the life or performance desired. Since the part seldom ruptures in actual practice except in instances of inadvertent overheating or overstressing, proper allowance is made for dimensional changes of considerable magnitude. Table VI gives rupture-strength data for a number of the heat-resisting steels. The short-time tensile strengths given in Table V correspond to the first point on a stress-rupture curve.

Rupture testing is useful for evaluating the strength properties of steels, aside from the usefulness of data so derived for the engineering design of structures that are to be used at high temperature. In the longer stress-rupture tests, which ordinarily do not exceed about 2000 hours, continuous strain measurements may be taken so that accelerated creep data may be obtained. It is common practice to extrapolate stress-to-rupture data in order to give theoretical values for rupture at 10,000 and 100,000 hours. This can be a dangerous practice because many metals used at high temperature tend to become brittle under load and to change in microstructure with the passage of time; consequently, premature failure may result. Also the full extent of progressive oxidation or corrosion may not be detected in these relatively short-time tests. Changes in the slope of the stress-rupture curve indicate either surface instability (oxidation) or structural instability (carbide precipitation, grain growth, phase change). When such changes are detected in tests that last up to 1000 hours or slightly more, proper warning is given but there is no guarantee that the slope of the curve will remain constant during longer periods. Consequently the engineer must select suitable factors of safety and incorporate them in the design values. Ferritic alloys usually exhibit greater ability to elongate under stress than do alloys of austenitic structure, which may break short under stress at temperatures higher than about 1000 F.

Creep Strength. The creep test is well known and numerous data exist on steels and other metals. In the tensile creep test, specimens are maintained under precise temperature control and under constant load; the strain is measured and recorded at regular time intervals throughout the test, which is conducted under several stresses at each temperature for periods of at least 1000 hours, and in many tests 5000 to 10,000 hours. Individual specimens are used for each set of stress-temperature conditions. Some few tests have been extended to 100,000 hours. The secondary rate of creep is ascertained from the slope of the time-elongation curves, and the rate of creep at various stresses can be determined by log-log plotting versus stress. Commonly used values correspond to 0.10%, 0.01% and 0.001% creep per 1000 hours. These values are usually considered in terms of 1% elongation in 10,000 hours, 1% in 100,000 hours and 1% in 1,000,000 hours respectively, and are used in design after proper allowances have been made, in accordance with the specific service requirements and permissible deformation.

The carbon steels are satisfactory for service under low stresses at 800 F, and in some instances up to 1000 F; low-alloy steels are commonly used between 800 and 1100 F. Above 1100 F the extra strength and resistance to corrosion of the heat-resisting stainless steels generally become necessary. Table VII, which concerns the heat-resisting steels, contains averaged values of creep strength from several sources, for 1% elongation in 10,000 hours. This table includes typical supplementary data on stresses for 1% elongation in 100,000 hours. The stress required for producing a flow rate of 1% in 10,000 hours is greater

than, but not in direct proportion to, the stress required for 1% in 100,000 hours. Although frequently practiced, the extrapolation of these data to different temperature ranges, flow rates or compositions, is not recommended. Furthermore, the engineer should consider the heat treatment given and the grain size of the steel, in order to assay its specific creep properties.

The superior creep resistance of the austenitic steels indicates the advantage of this type of alloy for service at temperatures above 1000 F. Lighter weight structures, higher stresses, higher temperatures and, in general, more adequate factors of safety, are made possible through the use of such austenitic materials. Composition has an important influence and relatively small additions of such elements as molybdenum, aluminum and silicon have been observed to alter considerably the creep strength of the various chromium-nickel alloy steels. In the marginal austenitic alloys, this may be caused by ferrite formed as a result of the additional element. The unexpected decrease in creep resistance of the higher-chromium ferritic alloys at 1100 F and higher, is probably related to the peculiar aging phenomenon that occurs in this range, promoting the formation of sigma phase. It is generally believed that structural instability lowers creep resistance, although high recrystallization temperature and certain types of precipitation have a strengthening effect. However, it appears that fundamentally, the body-centered cubic crystal structure (ferrite or alpha) is less resistant to creep than the face-centered cubic structure (austenite or gamma). The austenitic heat-resisting steels are greatly superior, therefore, in load-carrying ability.

Fatigue Stresses. Alternating stresses and fluctuations of temperature accelerate creep in metals at high temperature. Similarly, rapid intermittent stresses (fatigue stresses) may have a detrimental effect at elevated temperature, especially in the range where the steels are relatively rigid and stress is not relieved quickly by plastic flow. Since pulsating or alternating stresses occur at elevated temperature in some types of service, further research on this subject appears advisable. Information about the subject is relatively scanty. The data given in Table VIII indicate the effect of temperature on endurance properties.

Physical Properties and Characteristics. Relevant data concerning the physical properties and characteristics of annealed heat-resisting steels are listed in Table IX.

Although the useful life of the heat-resisting steels may be judged on the basis of their oxidation resistance and properties of rupture strength and creep strength at high temperatures, nevertheless other characteristics also must be considered in order to estimate correctly the behavior of these steels at elevated temperatures. The expansion characteristics and magnetic properties may be altered to some extent by cold working, especially in borderline austenitic steels, although, as previously stated, these steels are generally used in the annealed condition. The thermal conductivity of the more highly alloyed steels varies with

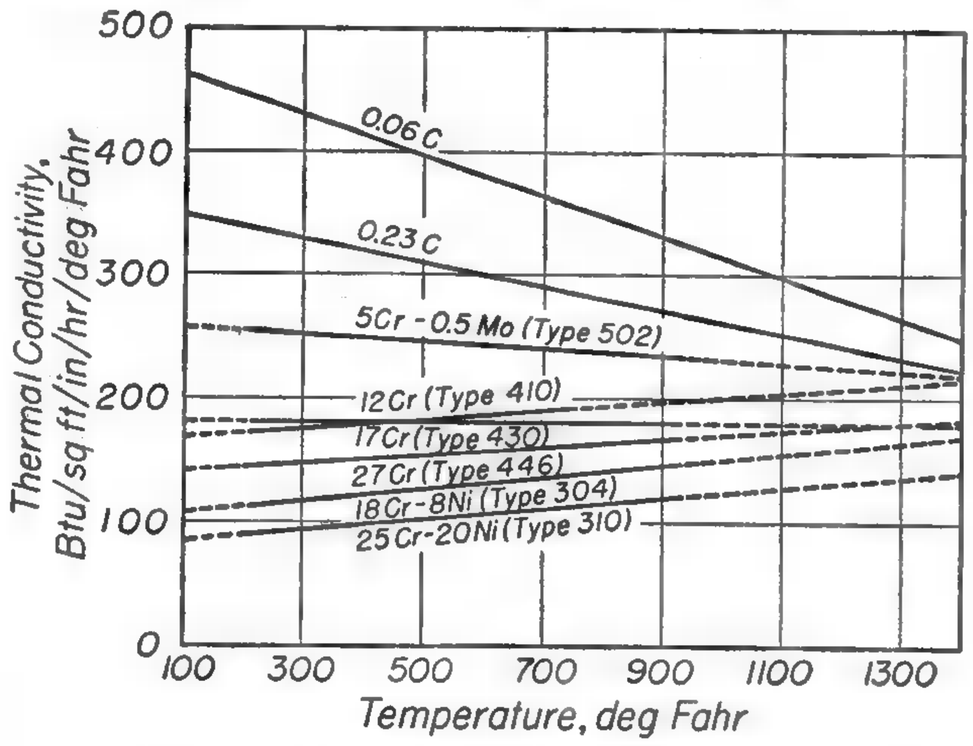

Fig. 1 Influence of temperature on the thermal conductivity of heat-resisting steels

temperature in approximately the manner shown in Fig. 1, where the conductivity of carbon steels is shown for comparison.

Design. In view of the variety of design problems involved in the application of these heat-resisting steels to structures and parts of high-temperature equipment, and because of the lack of uniform methods for applying safe stress values, it is obvious that each application is a problem in itself with regard to the selection of material for the particular service conditions and proper design for the expected life of the equipment.

The properties, behavior and application of the heat-resisting steels are becoming fairly well known and their utility and limitations are recognized. Applications in industry are made accordingly. For more detailed information, the reader may refer to the selected references listed at the end of this article.

Superstrength Wrought Heat-Resisting Alloys. Wartime requirements greatly accelerated the development and evaluation of heat-resisting alloys. These alloys have found their greatest use in rotors and buckets for turbosuperchargers and jet aircraft engines, but are also being used in the fabrication of gas turbines for marine power plants. In aircraft applications, the expected service life was short, and the alloys were evaluated principally on the basis of the stresses that produce rupture in 1000 hours. For longer service life, and particularly in those instances in which the allowable total deformation was limited to relatively low values, the alloys were evaluated by creep tests that lasted from 2000 to 2500 hours. The temperature range studied was from 1200 to 1800 F. High yield strength at room temperature was also needed in rotor materials, to withstand the high stresses produced in an overspeed inspection test.

A large number of alloys were supplied for test by industry, but only a few have received attention for commercial use. Many alloys not now in use varied little in composition. The data presented here are for a selected group of these heat-resisting alloys and serve to indicate both the alloys commanding the most attention and the range of properties available.

Table X shows the chemical compositions of the alloys for which the available stress-rupture and creep data are presented in Tables XI and XII. Except for alloy 19-9W-Mo these alloys are wholly austenitic.

All the alloys except Inconel "X" and Hastelloy B contain 18% Cr or more, with sufficient nickel to make the metal austenitic and to show adequate surface stability. The addition of cobalt appears necessary for the best strength in the higher temperature ranges. Molybdenum, tungsten and columbium are added singly or together to increase the strength of the alloys at high temperature. Three of the alloys—Inconel "X", K-42-B, and Refractaloy 26—are strengthened by precipitated phases produced by additions of titanium and aluminum. Hastelloy B contains no chromium and its use is restricted to about 1400 F. Vitallium, plain Inconel, and 25 Cr–20 Ni–1.5 Si (type 310) have been used in sheet form for combustion chambers and tail pipes on jet aircraft engines. The test data presented here were taken largely from the wartime research reported by J. W. Freeman, E. E. Reynolds, and A. E. White; and by Howard C. Cross and Ward F. Simmons; also from data in the files of the producers of heat-resisting alloys.

Space does not permit presentation of all the data obtained. The above-noted reports include short-time high-temperature tension test data for many of the alloys, as well as stress-rupture and creep data for the alloys in conditions not shown in Tables X, XI and XII.

The test data have shown that chemical composition alone does not determine the properties, but that fabrication procedure and heat treatment also are potent factors. For this reason many of the alloys were studied in several conditions of heat treatment and fabrication.

High yield strengths at room temperature were obtained only by so-called "hot cold working" the alloys about 20% or more at temperatures below 1700 F (usually near 1200 F) except in age hardening alloys of the Inconel "X" type. The best combination of strength and ductility both at room temperature and at 1200 F was generally

found in alloys forged or rolled down to temperatures between 1700 and 1200 F. Superior rupture strengths at 1200 F can be imparted by hot cold working after a solution treatment, but this procedure generally causes low ductility in the rupture tests. Hot cold worked materials have better load-carrying ability under high stresses and for short periods, while annealed or solution treated materials are better under low stresses for long periods.

At about 1350 F alloys that have been given a solution treatment, with or without aging treatments, usually develop the best properties. At 1500 and 1600 F, either hot or hot cold work develops properties inferior to those obtained from solution treated and aged alloys. The

(a) Data supplied by Research Laboratories of the Westinghouse Electric and Manufacturing Company

available data concerning large forged disks of several alloys, indicate that the properties of bar stock are virtually duplicated in large forgings when the processing and heat treatments are equivalent.

Comparison of properties of wrought and cast alloys indicates that above approximately 1350 F the alloys have better rupture strengths cast than forged.

These wrought heat-resisting alloys are much more difficult to machine and weld than either ferritic steels or the plain 18 Cr – 8 Ni steels.

The mechanism by which the various alloy compositions produce usable properties at high temperatures is not understood. Aging at temperatures of 1200 F or higher causes precipitation of phases whose identification is unknown except in a few alloys. Processing and fabricating procedures and heat treatment have been shown to influence the precipitation of these phases both before and during service at elevated temperature and under stress. Considerable experience has been acquired in producing most of the alloys for which data are shown, but it should be realized that the data presented are for the particular heats processed and heat treated as indicated.

Alloys K-42-B and Refractaloy 26 are strengthened by precipitation of phases produced by additions of titanium and aluminum. These alloys are among the strongest at 1350 F, and under high stresses at 1500 F. Under low stresses at 1500 F, they enter third-stage creep relatively early in a creep test, and the values shown for stresses for 0.0001 and 0.00001% per hour apply only to short-time service and should be used with caution.

Table XIII lists the high-temperature reversed-bending fatigue test data for many of the superstrength wrought heat-resisting alloys, as determined by the Research Laboratories of the Westinghouse Electric Company. Data are included for tests at 1200 and 1500 F on alloys heat treated as indicated in the table. It should be noted that for many of these alloys, the endurance strengths exceed the tension stresses that will produce rupture in 1000 hours at the same temperatures.

Research is continuing on these superstrength alloys, and as more fundamental information about their behavior is obtained, the alloys known at present may be improved by better techniques for processing or heat treatment, and still better new alloys may be developed.

Heat-Resistant Castings

BY THE SUBCOMMITTEE ON HEAT-RESISTANT CASTINGS*

CASTINGS are classed as heat-resistant if they are capable of sustained operation when exposed, either continuously or intermittently, to operating temperatures that create metal temperatures in excess of 900 F. Alloys used in castings for such service may be considered in the following groups: iron-chromium ("straight chromium" alloys), iron-chromium-nickel, nickel-chromium base, nickel-molybdenum base, cobalt base, and chromium base.

Many alloys of the same general type are used also for their resistance to corrosive mediums at temperatures below 900 F, and castings intended for such service are

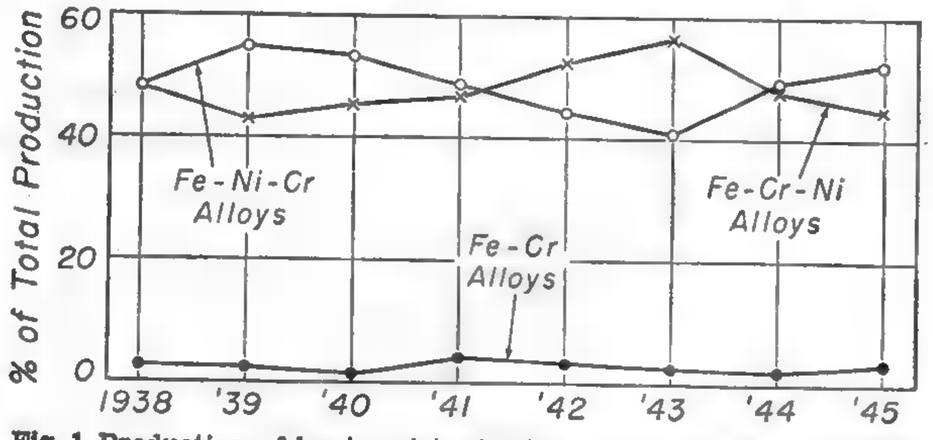

Fig. 1 Production of heat-resistant alloys (Alloy Casting Institute)

classed as corrosion-resistant. Although there is usually a distinction between the alloys of the two classes, based on carbon content, the line of demarcation is rather vague, particularly in the range from 900 to 1200 F. Thus the terms "heat-resistant" and "corrosion-resistant" are relative and are differentiated arbitrarily by the operating temperature of the material.

Heat-resistant castings, as defined, are used in metallurgical furnaces, oil-refinery furnaces, cement-mill furnaces, power-plant equipment, turbosuperchargers, gas turbines, and the manufacture of synthetic rubber.

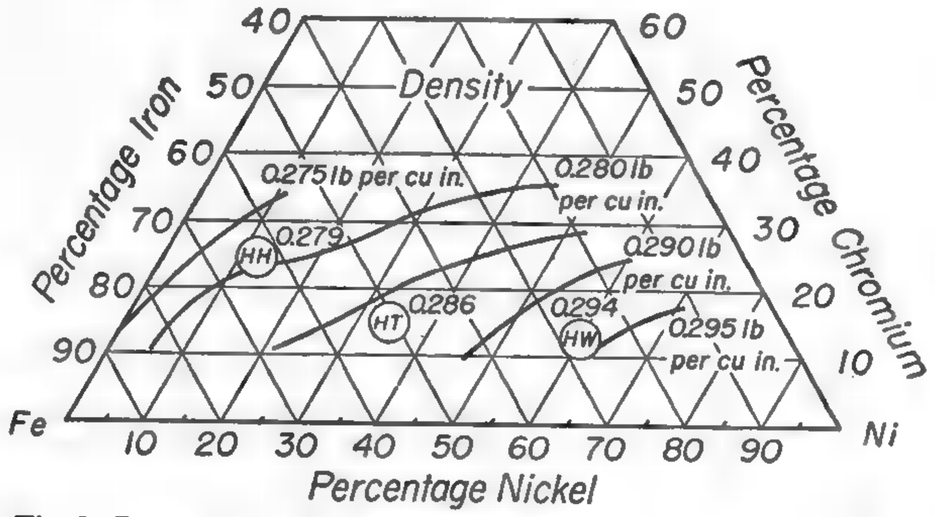

Fig. 2 Density of Fe-Cr-Ni alloys in pounds per cubic inch. Alloys also contained about 0.45% C, 1.25% Si and 0.80% Mn (Alloy Casting Institute)

During World War II special heat-resistant alloys were developed and produced in large quantities for use in military equipment, but the major commercial application is in furnaces for the treatment of metals. Alloys of the iron-chromium and iron-chromium-nickel groups are of the greatest commercial importance; these divide into three general categories, according to the major alloying element. The percentage of total production of these alloys accounted for by each group in recent years is shown in Fig. 1.

General Properties of Iron-Chromium and Iron-Chromium-Nickel Alloys. The general characteristics of the three types of heat-resistant iron-chromium and iron-chromium-nickel alloys are as follows:

1 Iron-chromium alloy castings that contain from 10 to 30% Cr and little or no nickel.

These alloys are useful chiefly for resistance to oxidation. They have low strength at elevated temperatures. The use of these alloys is dictated by conditions, either oxidizing or reducing, that involve low static loads and uniform heating. The chromium content depends on the temperature to which the alloys are to be exposed in service.

2 Austenitic alloys that contain more than 18% Cr and more than 5% Ni—always more chromium than nickel.

These alloys are used ordinarily under oxidizing or reducing conditions similar to those withstood by the iron-chromium alloys, but in service they have greater strength and ductility than the straight chromium alloys. They are used, therefore, to withstand greater loads and moderate changes of temperature. These alloys are also used in the presence of reducing gases that contain sulfur.

3 Austenitic alloys that contain more than 10% Cr and more than 25% Ni—always more nickel than chromium.

These alloys are used for withstanding a reducing as well as an oxidizing atmosphere, except where sulfur content is appreciable (for example, 0.05% H_2S or more). In such atmospheres the iron-chromium-nickel alloys of type 2 are recommended. The type 3 alloys do not carburize rapidly or become brittle and do not take up nitrogen in a nitriding atmosphere, in contrast with type 2 alloys. These properties become enhanced as the nickel content increases, and in carburizing and nitriding atmospheres the life of the casting increases with the nickel content. Austenitic ferrous alloys are used extensively under conditions of severe temperature fluctuations like those encountered by fixtures used in quenching and by parts that are not heated uniformly or that are heated and cooled intermittently. In addition these alloys have characteristics of electrical resistance that make them suitable for electrical resistor heating elements.

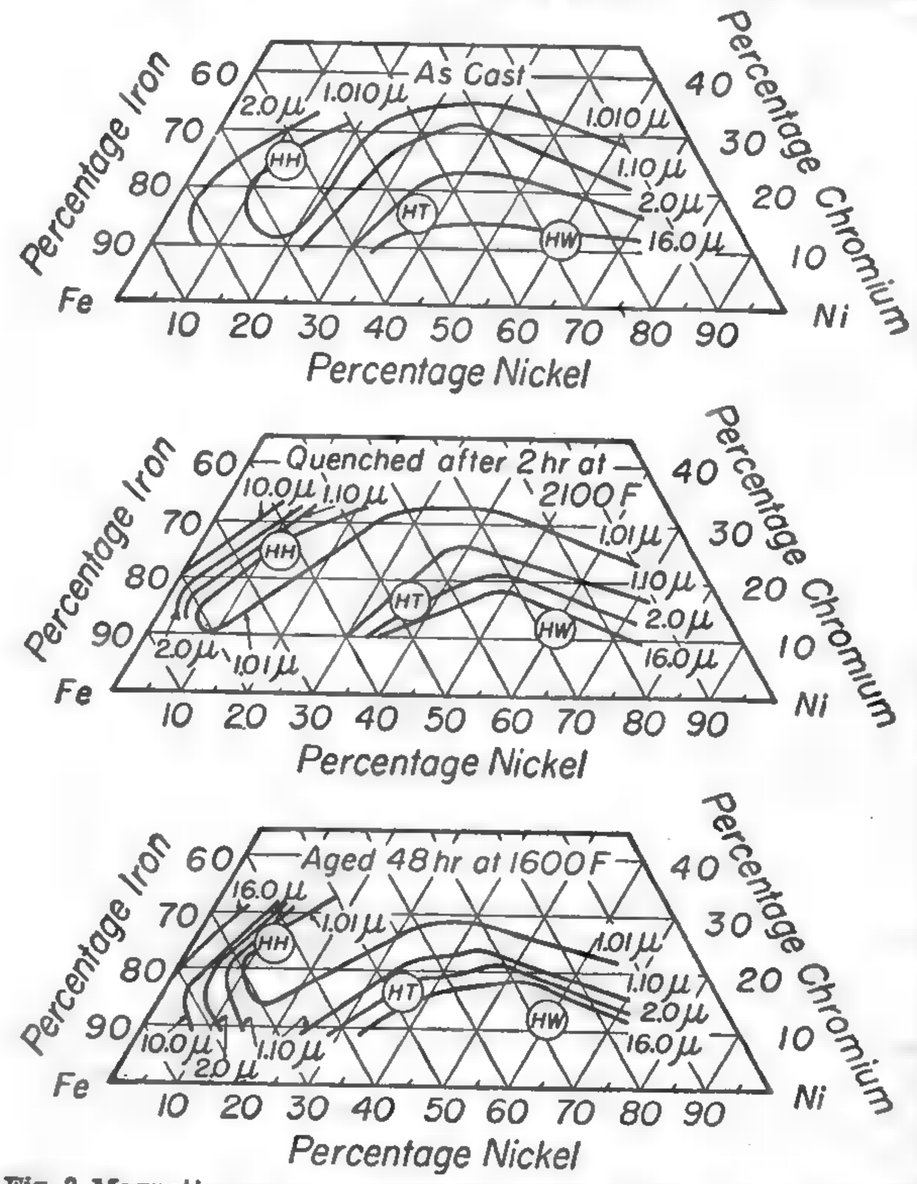

Fig. 3 Magnetic permeability of Fe-Cr-Ni alloys. Alloys also contained about 0.4% C, 1.25% Si and 0.80% Mn (Alloy Casting Institute)

Figures 2 and 3, showing density and magnetic permeability, have been plotted from data obtained in an extensive investigation of these alloys, sponsored by the Alloy Casting Institute. The approximate rates of corrosion in Table I were determined in the same research program. Table II gives mean coefficients of thermal expansion for the more commonly used alloys.

Manufacture. Castings produced in these several compositions may be made from heats melted in an electric-arc

furnace that has either an acid or a basic lining; or in a high-frequency induction furnace. Care must be used in producing sound, satisfactory castings; foundries producing such castings have developed special techniques for this work. Castings may be made by the static method, by centrifugal pouring or by the precision casting practice (*see* page 54). The centrifugal method is used extensively in the production of tubes for radiant heating furnaces and for other tubular parts.

With the exception of a small tonnage of iron-chromium alloys, the heat-resistant castings are not usually heat

Table II. Thermal Expansion of Commercial Heat-Resistant Castings

ACI Type	Mean Composition % Ni	% Cr	Mean Coefficient of Linear Thermal Expansion: Temp, °F	Per °F

treated before shipment. When the 12 and 18% Cr alloys are used, it is sometimes necessary to give the castings a full annealing treatment to remove casting stresses, because these two alloy grades are hardenable.

Properties of Iron-Chromium Alloys. "Straight chromium" alloys are made in the compositions listed in Table III.

Type CA (12% Cr). This alloy is a heat treatable ferritic-martensitic material used in considerable tonnage in corrosion-resistant applications, but to only a minor extent for heat-resistant castings. This alloy, however, contains enough chromium to make it suitable for applications at temperatures as high as 1250 F providing stresses are low. The mechanical properties of the alloy

Table III. Composition Limits of Iron-Chromium Heat-Resistant Castings

ACI Type	Composition, percentage: Carbon	Manganese	Silicon	Chromium	Nickel
CA	0.15 max	1.00 max	1.5 max	11.5 to 14	1.0 max
HB	0.30 max	1.00 max	2.0 max	18 to 22	2.0 max
HC	0.50 max	1.00 max	2.0 max	26 to 30	4.0 max
HD	0.50 max	1.50 max	2.0 max	26 to 30	4 to 7

at room temperature depend on the heat treatment. For high-temperature service, castings are given ■ full anneal.

Nominal values for the mechanical properties of annealed castings at room temperature are as follows:

Tensile strength	95,000 psi
Yield point	65,000 psi
Elongation in 2 in.	25%
Brinell hardness number	170

Type HB (18% Cr). This alloy is only slightly hardenable and is ferritic. It contains enough chromium to make it suitable for castings that are to resist oxidation up to temperatures of 1500 F. Castings are usually air-cooled from a temperature between 1400 and 1500 F and are

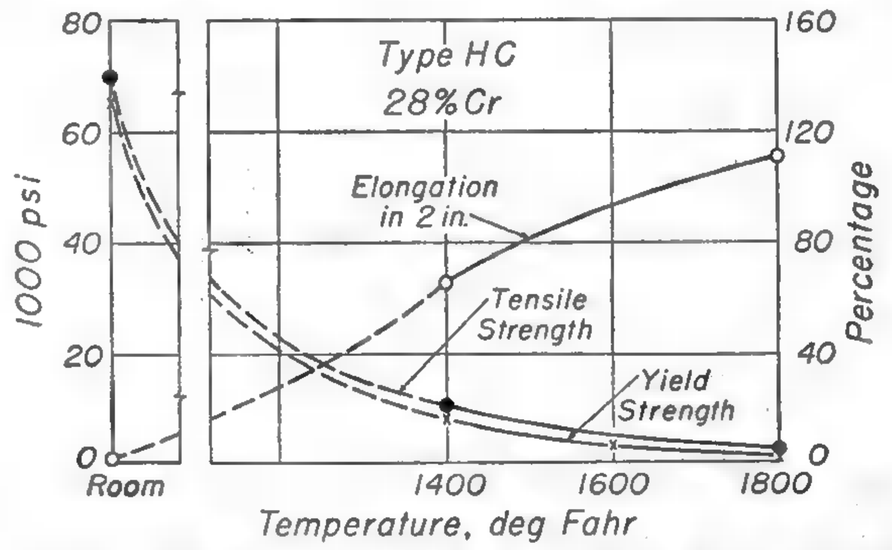

Fig. 4 Influence of temperature on the tensile strength, yield strength and elongation of Type HC (28% Cr) alloys

furnished in the annealed condition. Nominal mechanical properties at room temperature are as follows:

Tensile strength	75,000 psi
Yield point	50,000 psi
Elongation in 2 in.	25%
Brinell hardness number	170

Type HC (28% Cr). This alloy is used primarily for heat-resistant applications where strength is not a consideration, in high-sulfur atmospheres, and in some services where the presence of nickel cannot be tolerated. This alloy resists oxidation up to 2000 F. Castings are supplied in two carbon ranges: (1) 0.50% C max, used

Table IV. Mechanical Properties of Type HC Alloys (28% Cr, 0.50% C max)

Property	Normal Nitrogen	High Nitrogen
Tensile strength, psi	70,000	110,000
Yield strength, psi	65,000	75,000
Elongation, % in 2 in.	2	19
Brinell hardness number	179	223

Table V. Composition Limits of Iron-Chromium-Nickel Heat-Resistant Castings Containing More Chromium than Nickel

ACI Type	Composition, percentage				
	Carbon	Manganese	Silicon	Chromium	Nickel
HF	0.20 to 0.40	2.0 max	2.0 max	18 to 23	8 to 12
HE	0.20 to 0.50	2.0 max	2.0 max	26 to 30	8 to 11
HH	0.20 to 0.50	2.0 max	2.0 max	24 to 28	11 to 14
HI	0.20 to 0.50	2.0 max	2.0 max	26 to 30	14 to 18
HK	0.20 to 0.60	2.0 max	3.0 max	24 to 28	18 to 22
HL	0.20 to 0.60	2.0 max	3.0 max	28 to 32	18 to 22

for normal high-temperature service; and (2) 3.00% C max, used where a hard material resistant to abrasion is required for high-temperature service.

The nominal mechanical properties at room temperature of the 28% Cr alloy containing 0.50% C max are shown in Table IV. The ductility and ultimate strength of this alloy are improved by the addition of nitrogen in excess of 0.15%, when more than 2% Ni is present.

The high-nitrogen alloy differs from the normal-nitrogen alloy in Table IV, in that the nickel content is higher than 2% and the nitrogen content is higher than 0.15%.

The Type HC alloys, when heated for prolonged periods in the range of temperatures from 750 to 1025 F, are embrittled and show low resistance to impact.

The curves in Fig. 4 show the nominal properties of the alloy as determined from short-time tests at elevated temperatures.

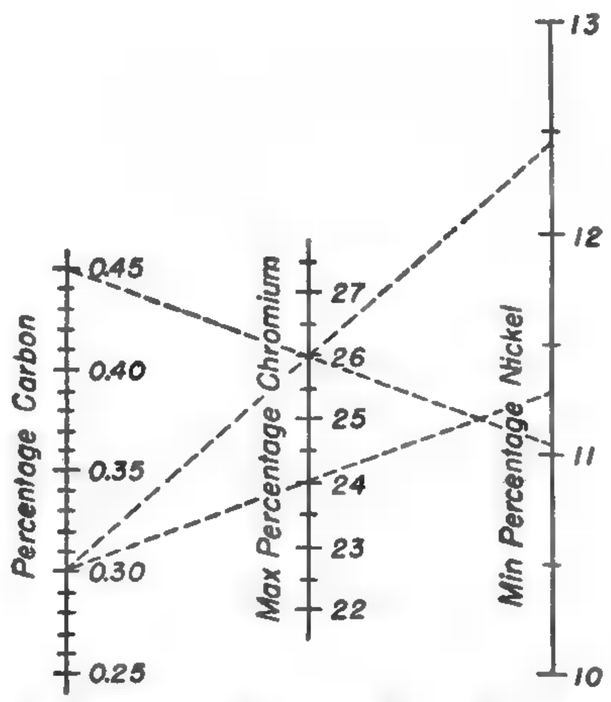

Fig. 5 Nomographic chart of chromium, nickel and carbon contents for wholly austenitic Type HH (25% Cr, 12% Ni) alloys (Gow and Harder[2])

Type HD (28% Cr, 5% Ni). This alloy is similar to the HC grade, except that the higher nickel content imparts somewhat greater strength at high temperatures.

Properties of Iron-Chromium-Nickel Alloys. Ferrous alloys in which the chromium content exceeds the nickel content are made in the compositions shown in Table V.

Type HF (20% Cr, 10% Ni). This alloy is essentially the same as the well-known 18% Cr, 8% Ni composition widely selected for its resistance to corrosion. The type HF alloy is also suitable for use at temperatures up to 1600 F. When used for resistance to oxidation at elevated temperatures, it is not necessary to keep the carbon content at the low level specified for corrosion-resistant castings. The nominal mechanical properties of the material at room temperature, without special additions of alloying elements, are given in Table VI. Molybdenum, tungsten, columbium and titanium are sometimes added to the normal type HF composition to impart greater strength at elevated temperatures.

Table VI. Mechanical Properties of Type HF Alloys (20% Cr, 10% Ni)

Property	As Cast	After 24 hr at 1400 F, Furnace Cooled
Tensile strength, psi	80,000	100,000
Yield strength, psi	45,000	50,000
Elongation, % in 2 in.	35	25
Brinell hardness number	170	192

Type HE (29% Cr, 10% Ni). This alloy has excellent resistance to corrosion at elevated temperatures. Because of the higher chromium content, this alloy can be used at higher temperatures than the HF type and is suitable for applications up to 2000 F. The material is stronger and more ductile at room temperatures than the straight-chromium types. Nominal mechanical properties at room temperature in the as-cast condition are as follows:

Tensile strength	85,000 psi
Yield strength	45,000 psi
Elongation in 2 in.	10%
Brinell hardness number	201

In recent years, as described hereafter, a great deal of work on the HH type alloy has provided a basis for evaluating the effect of variations in composition within the group of Fe-Cr-Ni alloys similar to type HH. Type HE belongs to this group.

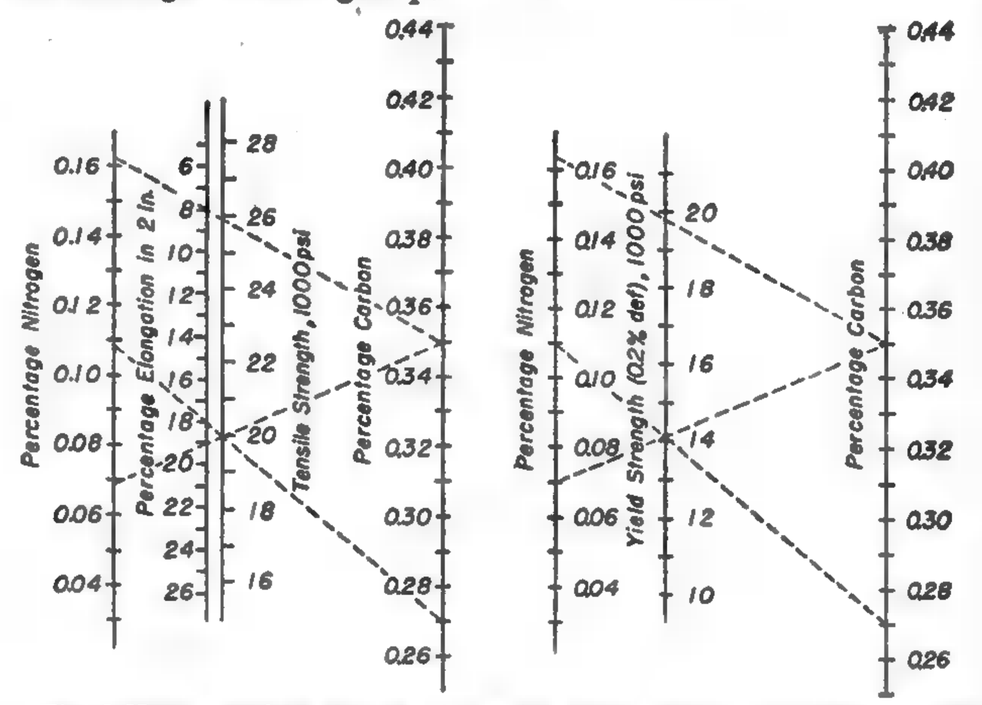

Fig. 6 Nomographic charts of results from short-time tension tests at 1600 F, showing elongation, tensile strength and yield strength in relation to carbon and nitrogen contents of Type HH (25% Cr, 12% Ni) alloys (Gow and Harder[2])

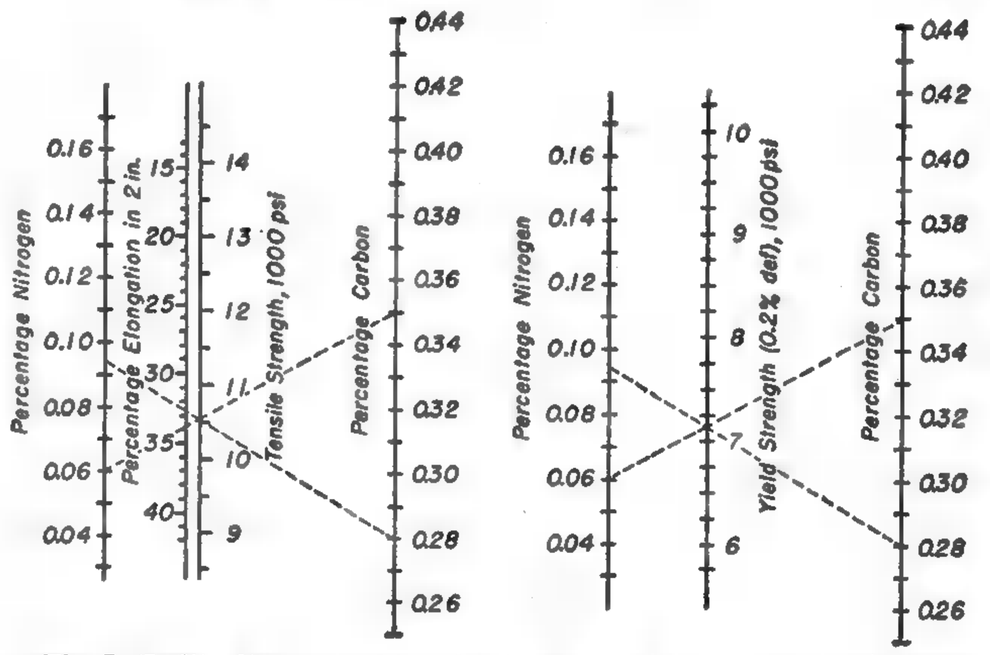

Fig. 7 (Left) Nomographic chart of the elongation and tensile strength at 1800 F in relation to carbon and nitrogen contents of Type HH (25% Cr, 12% Ni) alloys (Gow and Harder[2])

(Right) Nomographic chart of the yield point at 1800 F in relation to carbon and nitrogen contents of Type HH (25% Cr, 12% Ni) alloys (Gow and Harder[2])

Type HH (25% Cr, 12% Ni). Alloys of the nominal composition 25% Cr, 12% Ni, comprise about one third of the total production of heat-resistant castings. This material is used extensively in high-temperature applications, because of its strength and its resistance to oxidation at temperatures up to 2000 F.

Balancing the Composition of Type HH Alloys. The composition of this type of alloy is critical. As pointed out by Foley,[1] the range of nickel and chromium contents lies at the junction of the alpha plus gamma, the gamma, and the gamma plus sigma regions of the Fe-Cr-Ni sys-

Table VII. Mechanical Properties of Type HH Alloys (25% Cr, 12% Ni)

Property	As Cast	After 24 hr at 1400 F, Furnace Cooled
Tensile strength, psi	70,000 to 95,000	80,000 to 100,000
Yield strength, psi	35,000 to 50,000	40,000 to 55,000
Elongation, % in 2 in	15 to 30	4 to 20
Brinell hardness number	150 to 210	180 to 250

tem at 1650 F. Consequently, relatively large amounts of ferrite-promoting elements, in comparison with the amounts of austenite-promoting elements, may result in the presence of substantial amounts of ferrite in the metal. The presence of ferrite decreases the strength at high temperatures, and if the ferrite transforms to sigma at intermediate temperatures, castings may suffer from brittleness or cracking when held within certain temperature ranges or when heated and cooled repeatedly through these ranges.

To achieve maximum strength at high temperatures and good retained ductility, it is necessary that this alloy be essentially austenitic. If a balance is maintained between ferrite-promoting elements, such as chromium and silicon, and austenite-promoting elements, such as nickel and carbon, the desirable austenitic structure can be obtained. In commercial alloys of the HH type, with the usual carbon, nitrogen, manganese and silicon contents, Gow and Harder[2] found that the ratio of chromium to nickel necessary to ensure a stable austenitic alloy is expressed by the formula:

$$\frac{\text{Cr (\%)} - 16\ \text{C (\%)}}{\text{Ni (\%)}} = \text{less than } 1.7$$

The work of Gow and Harder provides strong evidence of the effect of silicon and molybdenum on the presence of sigma. Silicon in excess of 1% has the effect on structure of three times its weight in chromium, and molybdenum has the effect of four times its weight in chromium.

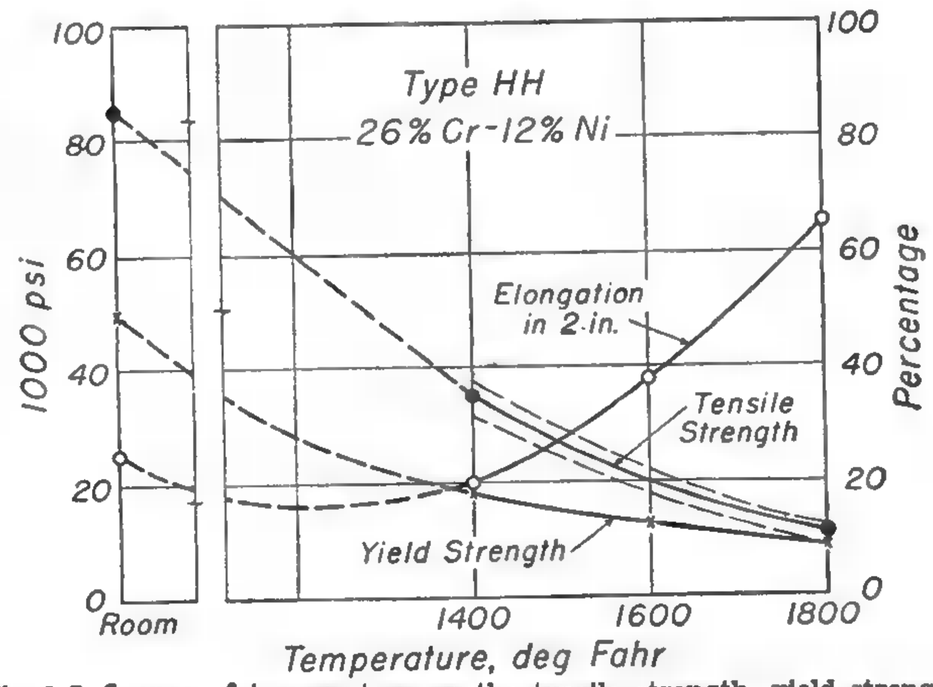

Fig. 8 Influence of temperature on the tensile strength, yield strength and elongation of Type HH (26% Cr, 12% Ni) alloys

After the metal has been heated between 1200 and 1600 F, loss in ductility results from two changes within the alloy: (1) precipitation of carbides and (2) transformation of ferrite to sigma. Obviously, when the composition of the alloy is balanced so that the structure is wholly austenitic, only the carbide precipitation occurs. In partially ferritic alloys, both carbides and sigma phase may form.

Figure 5, showing the relationship of carbon, chromium and nickel in the wholly austenitic HH type alloy, will be found useful in balancing the composition to obtain an austenitic structure.

Before selecting the HH type alloy as material for heat-resistant castings, it is advisable to consider the relation between the chemical composition and the temperature range in which the castings must operate. If castings are to operate continuously at a temperature appreciably above 1600 F, there is little danger of serious embrittlement from either carbide precipitation or sigma phase. In this instance the composition of the alloy may be 0.50% C max (0.35 to 0.40% preferred), 10 to 12% Ni and 24 to 27% Cr. On the other hand, if the operating temperature is to be from 1200 to 1600 F, the composition should be 0.40% C max, 11 to 14% Ni and 23 to 27% Cr. In all alloys, the composition should be balanced to provide an austenitic alloy; for instance, for the 1200 to 1600 F application, the use of 11% Ni with 27% Cr is likely to produce sigma phase and its associated embrittlement, which occurs most rapidly around 1600 F. It is better,

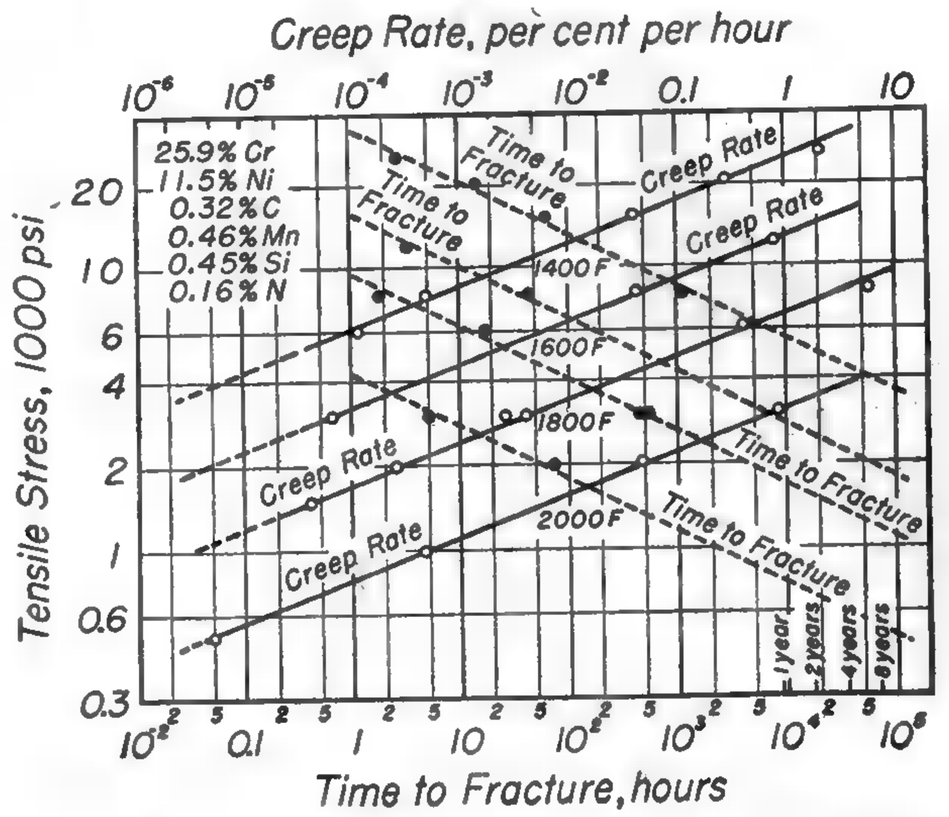

Fig. 9 Creep and rupture characteristics from 1400 to 2000 F of a Type HH (26% Cr, 12% Ni) alloy (Avery, Cook and Fellows[3])

therefore, not to use the maximum chromium content with the minimum nickel content.

Mechanical Properties of Type HH Alloys. The mechanical properties of the HH type alloy at room temperature vary considerably with the composition (Table VII).

Short-time tests of properties of austenitic HH type alloys at elevated temperatures, show that the tensile strength and elongation depend on the carbon and nitrogen contents. The nomographic charts in Fig. 6 and 7 may be used to determine the properties of these alloys at 1600 and 1800 F. Figure 8 shows curves of nominal mechanical properties for this alloy, as determined from short-time tests at elevated temperatures.

Table VIII. Chemical Compositions of Type HH Alloys Tested in Creep (Gow and Harder[2])

* A = Austenite, PF = Partially Ferritic

(a) AD showed a minimum creep rate of 0.15 between 100 and 300 hr

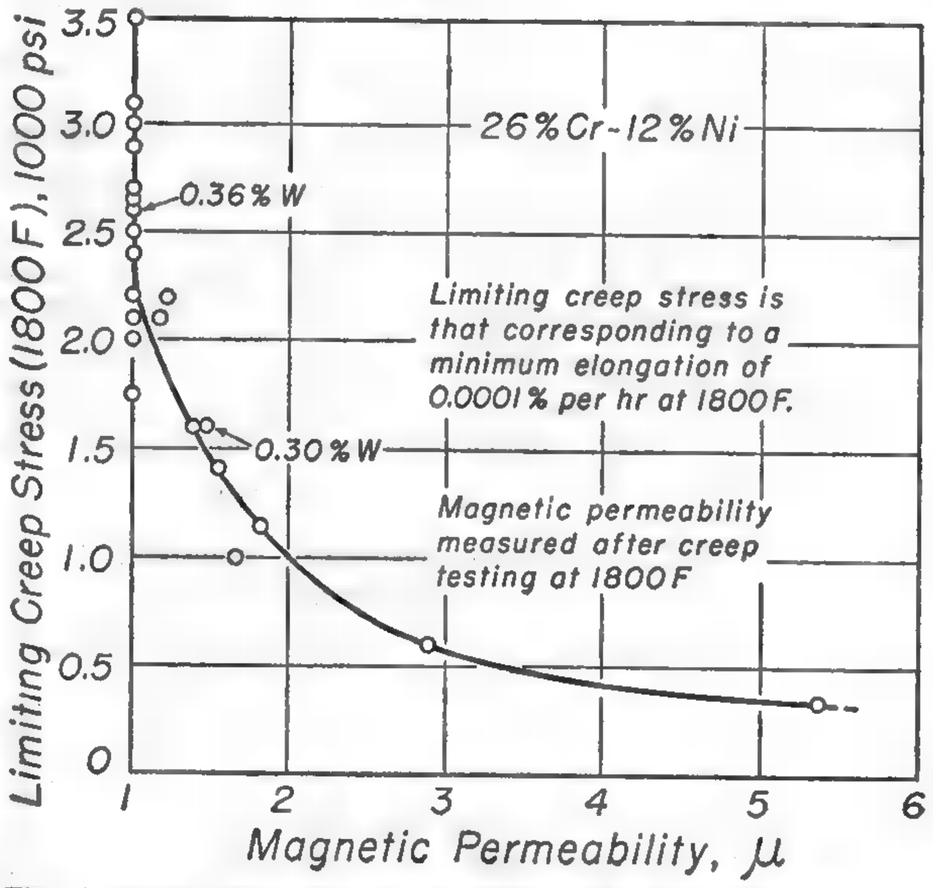

Fig. 10 Correlation of creep strength with magnetic permeability after creep testing of a Type HH (26% Cr, 12% Ni) alloy (Avery, Cook and Fellows[3])

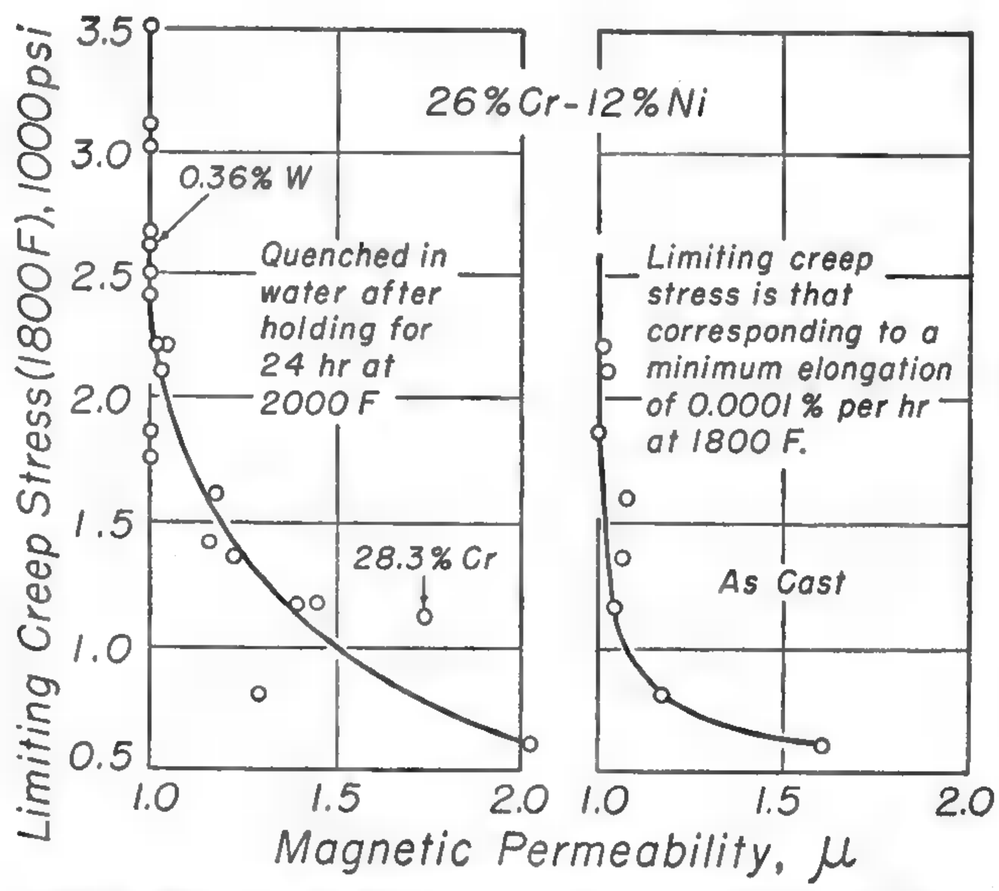

Fig. 11 Correlation of creep strength with permeability of unstressed specimens of a Type HH (26% Cr, 12% Ni) alloy (Avery, Cook and Fellows[3])

In the application of heat-resistant alloys, the considerations include (1) resistance of the alloy to corrosion at elevated temperature; (2) the stability of the alloy—that is, its resistance to warping, cracking or thermal fatigue; (3) the resistance of the alloy to plastic flow—that is, its creep strength. Research conducted at Battelle Memorial Institute for the Alloy Casting Institute, has indicated that for maximum creep strength the HH type alloy should be essentially austenitic in structure. Tables VIII to XI contain creep data for a number of alloys.

In the design of load-carrying castings, data concerning creep stresses should be used with an understanding of the limitations of these data. Avery, Cook and Fellows[3] have pointed out: "There is danger in assuming that an extrapolated L.C.S. (Limiting Creep Stress) for 1% elongation in 10,000 hours can necessarily be sustained for that length of time without structural damage." These authors suggest that stress-rupture tests are a valuable adjunct to creep tests and are useful in the selection of suitable design stresses. A comparison of creep rates and fracture times at various stresses and temperatures is shown in Fig. 9 for a wholly austenitic alloy.

As pointed out before, HH type alloys of wholly austenitic structure have greater strength at high temperatures than alloys of similar composition but of a partially ferritic structure. Although a ratio factor of less than 1.7,

Table X. Comparison of Creep Rates of Wholly Austenitic and Partially Ferritic Type HH Alloys at 1800 F Under a Load of 2000 psi (Gow and Harder[2])

See Table VIII for chemical compositions of alloys

Alloy No.	Microstructure	Min Creep Rate, per cent per hour × 1000
AD	Austenitic	0.045
AE	Austenitic	0.035

AT2	Partially ferritic	0.100
AN2	Partially ferritic	0.667 avg 0.304

calculated from the nickel, chromium and carbon contents, is an indication of a wholly austenitic material, ratio factors greater than 1.7 do not give a quantitative indication of the amount of ferrite present. It is possible, however, to measure the amount of ferrite in the material by magnetic analysis, after quenching the alloy from about 2000 F.

The magnetic permeability of HH type alloys increases with the amount of the ferrite phase. Thus, preferably after holding the alloy 24 hours at 2000 F and then quenching it in water, measurement of magnetic permeability can be related to the creep strength of the alloy, since this property depends also on the structure of the material. Figures 10 and 11 show the correlation between limiting creep stress and magnetic permeability.

The curves in Fig. 12 show the limiting creep stress for 0.0001% per hour minimum rate for alloys that have magnetic permeabilities between 1.00 and 1.70μ.

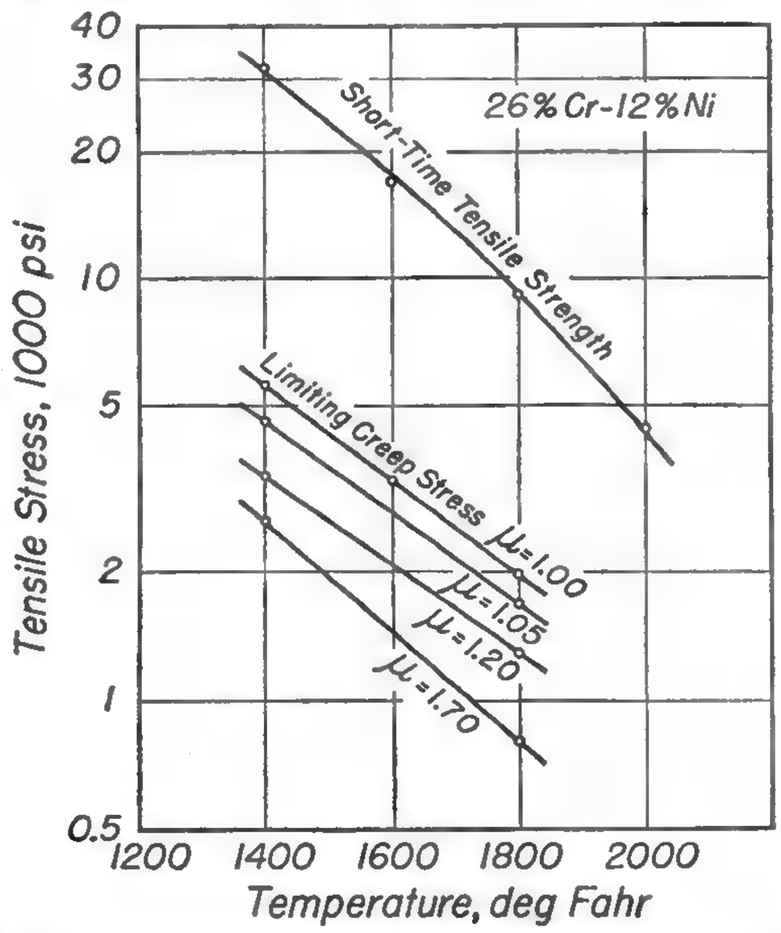

Fig. 12 Limiting creep stress for 0.0001% per hr minimum rate for Type HH (26% Cr, 12% Ni) alloys having magnetic permeabilities between 1.00 and 1.70 μ (American Brake Shoe Company)

Table XI. Comparison of Creep Rates of Wholly Austenitic and Partially Ferritic Type HH Alloys at 1600 F Under a Load of 4000 psi (Gow and Harder[2])

See Table VIII for chemical compositions of alloys

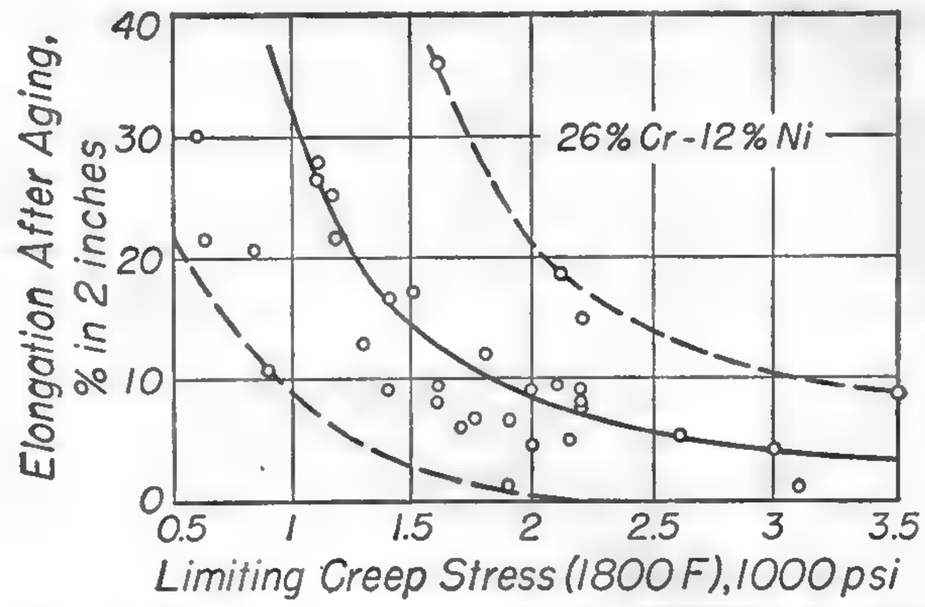

Fig. 13 Inverse relationship between creep strength and ductility after aging of Type HH (26% Cr, 12% Ni) alloy (Avery, Cook and Fellows[3]). Limiting creep stress is that corresponding to a minimum elongation of 0.0001% per hr. Elongation after aging was measured on specimens furnace cooled after being held for 24 hr at 1400 F.

Alloys of the HH type are often evaluated by comparing the percentage elongation of sample bars in a tension test at room temperature after the bars have been held 24 hours at 1400 F. Such a test may be misleading, since there is a tendency to favor compositions that produce the greatest elongation after this particular heat treatment. Avery, Cook and Fellows show that high ductility values are likely to be related to low creep resistance, as indicated in Fig. 13.

Type HI (28% Cr, 15% Ni). This alloy is similar to the HH type composition as far as mechanical properties and sensitivity of composition are concerned. However, the higher nickel and chromium contents increase the resistance of the material to oxidation. This alloy has been employed successfully at temperatures up to 2150 F.

Table XII. Comparison of Physical and Mechanical Properties of Type HH (26% Cr, 12% Ni) and Type HK (26% Cr, 20% Ni) Alloys[a][b]

Property	HH-32	HK-30
Nominal composition	26% Cr 12% Ni	26% Cr 20% Ni

1600 F	3,200	3,800
Recommended max tensile working stress, psi		
1400 F	2,900	2,900
1600 F	1,600	1,900

(a) Previously unpublished data, American Brake Shoe Company

(b) Both of these alloys are wholly austenitic, that is, they are free from ferrite and sigma.

Table XIII. Composition Limits of Iron-Nickel-Chromium and Nickel-Chromium-Base Heat-Resistant Castings

ACI Type	Composition, percentage				
	Carbon	Manganese	Silicon	Chromium	Nickel
HT	0.35 to 0.75	2.00 max	2.50 max	13 to 17	33 to 37
HU	0.35 to 0.75	2.00 max	2.50 max	17 to 21	37 to 41
HW	0.35 to 0.75	2.00 max	2.50 max	10 to 14	58 to 62
HX	0.35 to 0.75	2.00 max	2.50 max	15 to 19	64 to 68

Type HK (25% Cr, 20% Ni). The HK type alloy may be considered similar to a balanced HH type in general characteristics and mechanical behavior. The higher nickel content, strongly effective in the stabilization of austenite, removes the likelihood that either ferrite or sigma phase will develop at service temperatures, provided the carbon content exceeds 0.20%. Some low-carbon grades, similar to ranges characteristic of wrought products of this nominal composition, are subject to sigma embrittlement at certain temperatures around 1600 F.

Resistance of HK alloys to corrosion by hot gas is generally greater than that of the HH type, and in atmospheres containing 100 grains or more of sulfur per 100 cu ft of gas (0.016% SO_2), the HK compositions are superior to the high-nickel types HT and HW. Type HK thus appears as the most economical alloy for high resistance to oxidation and relative insensitivity to changes in alloy content. It is an excellent alloy for general structural applications at temperatures as high as 2100 F, and has substantial interchangeability with balanced HH alloys in design calculations. An extended comparison of properties of the HK and HH types is given in Table XII.

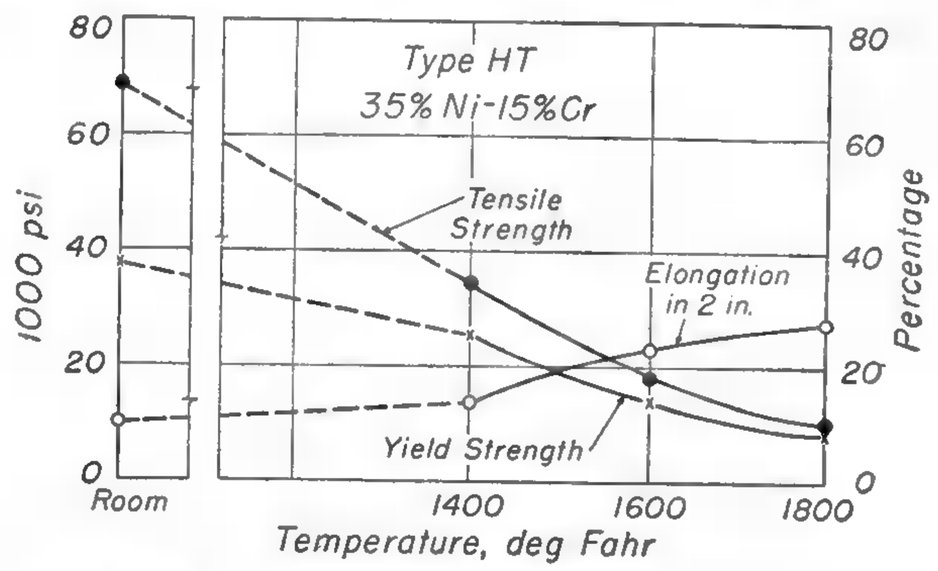

Fig. 14 Influence of temperature on the tensile strength, yield strength and elongation of Type HT (35% Ni, 15% Cr) alloys

Type HL (30% Cr, 20% Ni). This alloy is very similar to the HK type, except that the increase of chromium content to about 30%, places the composition in the alloy range indicated to be most resistant to corrosion at temperatures above 1800 F in atmospheres high in sulfur.

Properties of Iron-Nickel-Chromium and Nickel-Chromium-Base Alloys. Heat-resistant alloys in which nickel is either the predominant alloying element or actually the base material, form an important class of castings essential in equipment for the heat treating industry. Four types are of paramount importance. The composition ranges are indicated in Table XIII.

In general these alloys have a more stable structure than the compositions in which chromium is the predominant alloying element. There is no evidence of a phase change that would cause brittleness within certain ranges of temperature. Experimental data indicate that the composition limits are not critical, and for this reason the production of castings in these alloys does not require such close control with respect to composition as when alloys in the preceding Fe-Cr-Ni group are used.

Table XIV. Mechanical Properties of Type HT Alloys (35% Ni, 15% Cr)

Property	As Cast	After 48 hr at 1800 F, Air Cooled
Tensile strength, psi	69,000	75,000
Yield strength, psi	37,500	45,000
Elongation, % in 2 in	10	5
Brinell hardness number	192	197

Table XV. Mechanical Properties of Type HW Alloys (60% Ni, 12% Cr)

Property	As Cast	After 48 hr at 1800 F, Air Cooled
Tensile strength, psi	68,000	75,000
Yield strength, psi	36,000	38,000
Elongation, % in 2 in	4	4
Brinell hardness number	179	205

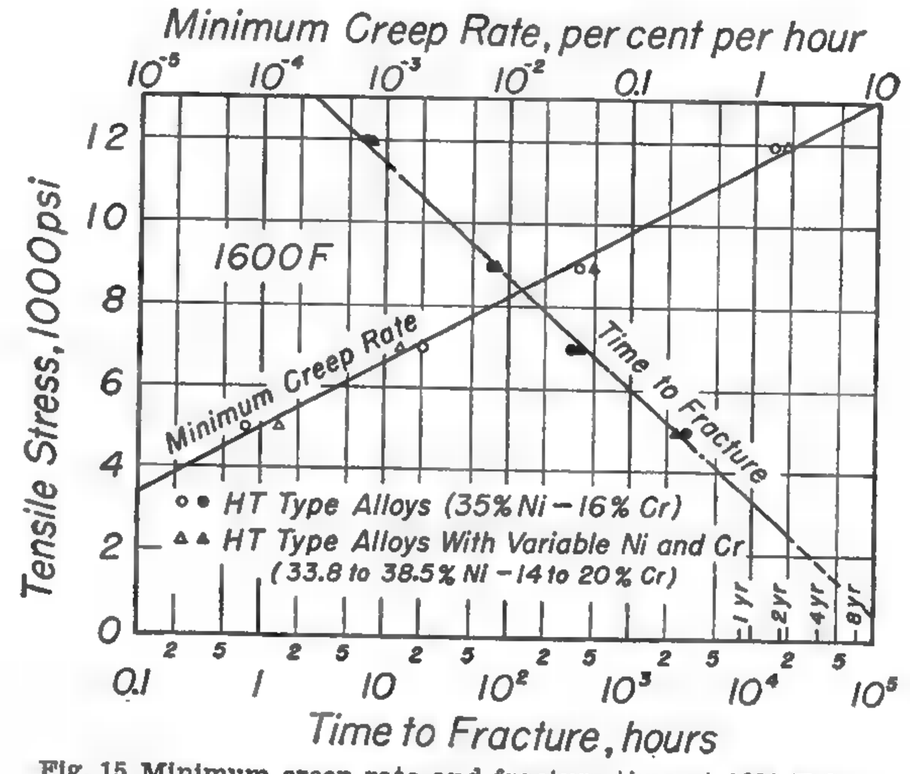

Fig. 15 Minimum creep rate and fracture time at 1600 F for Type HT (35% Ni, 16% Cr) alloys (Avery[4])

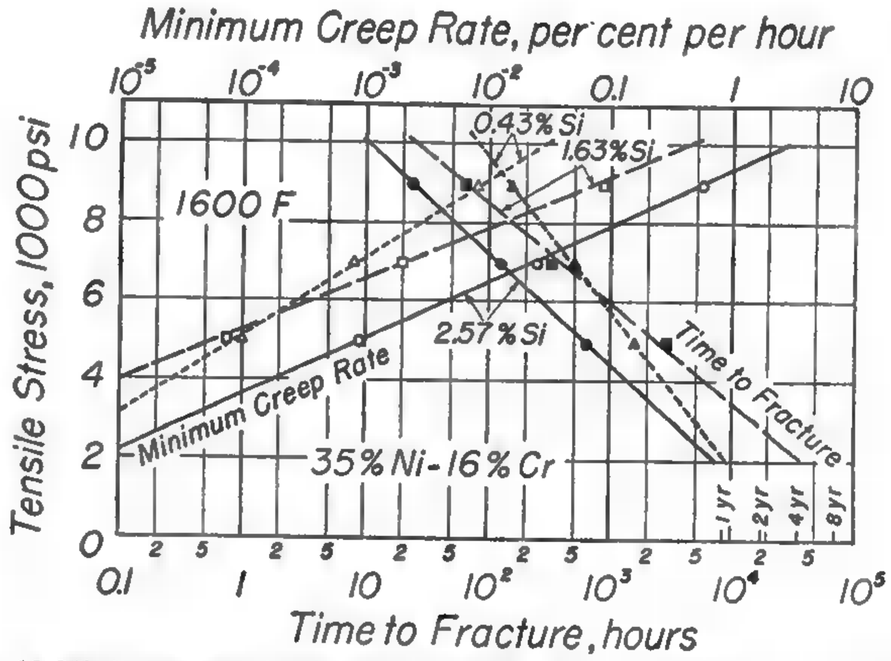

Fig. 16 Minimum creep rate and fracture time at 1600 F for Type HT (35% Ni, 16% Cr) alloys of three silicon contents (Avery[4])

Alloy types HT, HU, HW and HX as a group normally constitute more than 50% of the total production of heat-resistant alloys. These four alloys have given excellent service life in fixtures and trays for heat treating furnaces, where the castings are subjected to rapid heating or cooling.

Table XVI. Mechanical Properties of Type HX Alloys (67% Ni, 17% Cr)

Property	As Cast	After 48 hr at 1800 F, Air Cooled
Tensile strength, psi	75,000	82,000
Yield strength, psi	40,000	42,000
Elongation, % in 2 in	9	9
Brinell hardness number	170	183

Since these compositions carburize less readily than the Fe-Cr-Ni types, they are used extensively for parts in carburizing furnaces. Because they form an adherent scale that does not tend to fleck off, castings of high-nickel alloys are also made for the enameling industry, for applications where loose scale would be detrimental to the process.

In many respects there is no sharp line of demarcation between the HT, HU, HW and HX alloys as far as service applications are concerned. The following general observations, however, should be considered when the most suitable alloy is being selected for any given service.

1 As the nickel content is increased, the tendency for the alloys to carburize is decreased.
2 As the nickel content is increased, the tensile strength of the alloys at elevated temperatures is decreased somewhat, but the alloys are more resistant to thermal shock.
3 As the chromium content is increased, the alloys become more resistant to corrosion and oxidation.
4 As the carbon content is increased, the tensile strength of the alloys at elevated temperatures is increased.
5 As the silicon content is increased, the tensile strength of the alloys at elevated temperatures is decreased, but the resistance to carburization is increased somewhat.

Type HT (35% Ni, 15% Cr). This alloy is used far more widely than the others in which nickel and chromium are the dominant elements. The HT type is used for more than one-third of all the heat-resistant castings that are produced, and it is employed satisfactorily at temperatures up to 2100 F in oxidizing atmospheres and up to 2000 F in reducing atmospheres. Castings of this type are used in many heat treating furnace applications.

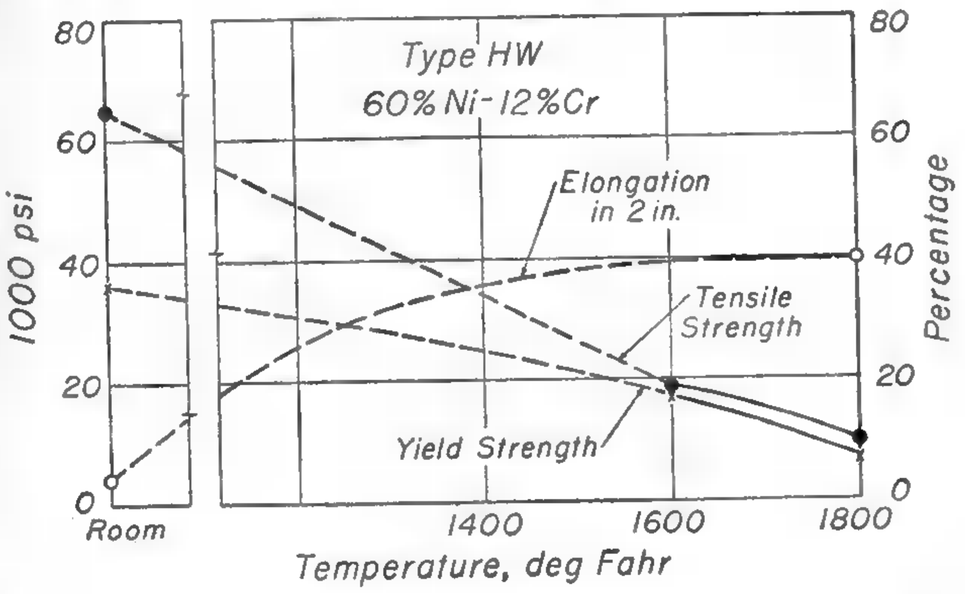

Fig. 17 Influence of temperature on the tensile strength, yield strength and elongation of Type HW (60% Ni, 12% Cr) alloys

Nominal mechanical properties of the HT type alloys at room temperature are listed in Table XIV.

Figure 14 presents a summary of the strength of the HT type alloys at elevated temperatures, as determined from short-time tension tests. Comparison of creep rates and fracture times,[4] are shown in Fig. 15 for alloys of the HT composition at 1600 F. The curves in Fig. 16 indicate the effect of silicon content in HT alloys on rate of creep and time to fracture.

Studies made with pack carburizing compounds indicate that HT type alloys may carburize rather rapidly as the silicon content is decreased below 1.5%. If carburization is to be kept at a minimum, the silicon should be not less than 1.25%.

Type HU (39% Ni, 19% Cr). This alloy is substantially the same as the HT composition with regard to mechanical properties. The increased chromium content, however, increases the strength somewhat at elevated temperatures. Under severe service conditions, this alloy is often recommended instead of the HT type, because the higher alloy content increases the resistance of castings to corrosive attack, as indicated in Table I.

Type HW (60% Ni, 12% Cr). Alloys of high nickel content, such as the HW type, are used extensively for retorts and furnace parts that require resistance to oxidation, carburization, nitriding and thermal shock. Because of their electrical resistivity, these compositions are also used for cast electrical heating elements. Although generally considered not quite so strong as the HT type alloys at elevated temperatures, the alloys of the HW type may be used in applications at temperatures up to 2050 F in oxidizing and up to 1900 F in reducing atmospheres.

Where hot gases have a high sulfur content, as in the products of combustion of high-sulfur fuels, the HW composition is likely to be attacked too severely, and alloys of the Fe-Cr-Ni type, such as HH or HL, are usually substituted. However, an increase in the chromium content to about 17%, increases the resistance of the high-nickel alloys to corrosion by sulfur-bearing gases, as stated in discussion of the HX type material, below.

Nominal properties of HW alloys at room temperature are presented in Table XV. Approximate properties, determined from short-time tests at elevated temperatures, are shown in Fig. 17.

Type HX (67% Ni, 17% Cr). This alloy is comparable in most respects with the HW type, but the higher nickel and chromium contents make the material more resistant to corrosion at elevated temperatures. As shown in Table I, the HX alloy is considerably better than the HW type in resistance to reducing gases that contain up to 100 grains of sulfur per 100 cu ft at 1800 F.

The mechanical properties of this alloy at room temperature are shown in Table XVI. Properties of the HX type at elevated temperature correspond to those given for the HW composition.

Alloys of both the HW and HX types are particularly useful because of their ability to withstand repeated heating and cooling without cracking or warping. For this reason they are employed extensively in severe service—for example, in quenching fixtures. The HW and HX alloys are highly resistant to carbon penetration in carburizing applications, and also have excellent resistance to corrosion when in contact with tempering salts and cyaniding salts. The HW and HX alloys are not recommended, however, for use in contact with the so-called "neutral" salts or with the salts used for heating high speed steel for hardening. Pots cast from these alloys have proved satisfactory as containers for molten lead.

General Remarks About Mechanical Properties. The properties shown for the various alloys are not necessarily indicative of the behavior of castings at elevated temperature. First, room-temperature data, either for the material in the as-cast condition or after exposure of the alloy to a high temperature for a short time, are only an indication of the soundness of the metal. Tests of a particular composition at room temperature are valuable, therefore, merely as confirmation that the alloy will behave at elevated temperatures in the same way that the *same composition* has behaved previously in the *same application.* Furthermore, short-time tests at elevated temperatures do not indicate the extent of the plastic deformation (creep) to which castings are subject in service; and for this reason, the values of stress shown by such tests could not be sustained by the materials for a prolonged time. Therefore, stresses used in designing castings for service at high temperature should be selected with due regard to the creep-strength characteristics of the material employed.

In the design of castings and in the selection of alloys, the safest course for the user is to consult the manufacturers of the alloys in order to obtain the benefit of their experience with similar applications. Faulty design, overloading or uneven heating are often factors of greater importance than alloy composition in determining the life of castings in service. It is most important that heat-resistant castings be designed to provide free expansion of the parts. Overlooking this point will inevitably result in the imposition of extremely high stresses that may crack or distort the structure.

Ni-Mo-Fe and Ni-Mo-Cr-Fe Alloys. The nickel-base alloys that contain high percentages of molybdenum as a primary alloying element were developed for their resistance to chemical corrosion. (*See* data in the NICKEL SECTION, pages 1054 to 1057.) However, these alloys also have good mechanical properties at high temperature and are used in the form of castings for certain high-temperature applications that warrant the cost of the alloys—higher than that of iron-base heat-resistant alloys. In regard to both cost and resistance to the effects of heat, these alloys

are intermediate between the iron-base and the cobalt-base heat-resistant alloys.

Table XVII. Composition Limits of Nickel-Molybdenum-Base Alloys

Alloy Designation	Composition, percentage				
	Ni	Mo	C	Fe	Other
Hastelloy A.....	55.5–59.5	18–22	0.04–0.15	18–22	.....
Hastelloy B.....	62.5–66.5	26–30	0.04–0.15	4–7	.....
Hastelloy C.....	54.5–59.5	15–19	0.04–0.15	4–7	13-16 Cr, 3.5–5.5 W

Compositions of the nickel-molybdenum-base alloys are shown in Table XVII. These alloys may be melted in either induction or electric-arc furnaces and may be cast by either gravity or centrifugal methods. They are particularly suitable for precision casting. The mechanical properties at room and elevated temperatures, shown in Table XVIII, were obtained from precision-cast test specimens 0.250 in. in diam, and the data on stress-to-rupture properties given in Table XIX were obtained from precision-cast specimens, 0.160 in. in diam. It should be noted, from

Table XVIII. Results of Short-Time Tension Tests of Nickel-Molybdenum-Base Alloys

(a) 0.2% offset

the compositions shown in Table XVII, that Hastelloys A and B contain no chromium. This limits the application of these two alloys under oxidizing conditions to a maximum temperature of about 1400 F. These two alloys are particularly satisfactory under reducing conditions. Hastelloy C, having a considerable chromium content, is useful for its resistance to oxidation at temperatures up to 2100 F, and is also satisfactory in atmospheres that are reducing or otherwise corrosive.

These alloys have given outstanding service in a wide variety of applications, such as Hastelloy A for fixtures and parts for continual or repeated submersion in cyaniding baths, including treatments where the heating is followed by quenching in water or in an acid pickling solution; Hastelloy C for tracks and trays for heat treating furnaces operating at temperatures up to 2000 F, as well as for chain conveyers in heat treating furnaces operating up to 1750 F, and for carburizing equipment. These three alloys are also available in the form of wrought material, which may be used with castings in the fabrication of heat treating parts.

Table XIX. Stress-to-Rupture Properties of Nickel-Molybdenum-Base Alloys at 1500 F

Precision-cast specimens, 0.160 in. in diam, tested after the heat treatments indicated

Alloy Designation	Heat Treatment	Stress (psi) for Rupture in			Longest Time to Fracture, hr
		10 Hr	100 Hr	1000 Hr	
Hastelloy A.....	(a)	19,500	11,600	8,800	1953
Hastelloy B.....	(a)	29,000	17,600	10,700	967
Hastelloy C.....	(b)	18,800	14,100	10,700	1222

(a) 2125 F for ½ hr, air cooled, 1700 F for 72 hr, air cooled
(b) 2225 F for ½ hr, air cooled, 2100 F for 8 hr, air cooled

Cobalt-Base Alloys. The cobalt-base high-temperature alloys were first used for highly stressed gas-turbine blading in 1941. The alloy first used was a modification of Vitallium, a dental alloy, employed for a number of years before World War II. The application and modification of the alloy and the production of gas-turbine blading by precision casting on an industrial scale were important wartime developments in the field of metallurgy. The process of precision casting is discussed in the article on page 54 of this Handbook. The wartime application of this alloy was at temperatures no higher than those at which the heat-resistant alloys of the Fe-Cr-Ni and Fe-Ni-Cr types were used, but the alloy served under conditions of high stress, and far surpassed the older alloys in stress-to-rupture strength and creep properties. Stellite 21 alloy, melting at 2547 F, has the highest melting point of this group of alloys. The further improvements on this alloy were obtained in part by an increase in the carbon content, decreasing the melting point by 50 to 100 F.

The cobalt-base high-temperature alloys, except for one, were used in the form of precision castings, although wrought products of sheet and in some grades of bar stock, have recently become available. However, the S-816 alloy was developed as a wrought material and has only recently been tested extensively in the cast form. The original use of Vitallium was based primarily on its high stress-to-rupture properties. Subsequent to the initial application and modification of Vitallium, an extended program of testing was carried out on high-temperature alloys of all types, to establish extensive data on their physical and mechanical properties and to encourage the development of improved alloys. This work was carried out on NDRC contract under the supervision of Battelle Memorial Institute, and on NACA contract under the supervision of the University of Michigan. These programs were of a highly co-operative nature, making use of testing facilities for high-temperature properties wherever such equipment was available throughout the United States. The data presented in this article (Tables XX to XXVII) were taken in large part from these results, although they have been expanded to some extent by test data of the manufacturers and the users, in order to give as complete data as possible concerning the physical and mechanical properties.

Table XX. Chemical Compositions and Densities of Cobalt-Base Heat-Resistant Castings

Original Designation	Composition, percentage									Density, lb per cu cm	Stellite Number
	C	Cr	Ni	Mo	Cb	W	Mn	Si	Fe		
Vitallium	0.25	27	■	6	..	..	0.60	0.60	1	8.30	21
61	0.40	23	2	..	..	5	0.60	0.60	1	8.54	23
6059	0.40	23	32	6	..	..	0.60	0.60	1	8.21	27
422-19	0.40	23	16	6	..	..	0.60	0.60	1	8.31	30
X-40	0.40	23	10	..	..	7	0.60	0.60	1	8.61	31
S-816	0.40	19	20	4	4	4	0.60	0.30	3	8.59	..

The use of cast alloys in preference to forged alloys is indicated by the superior properties in both stress-to-rupture and creep tests of long duration and at higher temperatures, as compared with the similar properties of wrought materials under these conditions. The short-time, high-temperature properties of the cast materials, however, are definitely lower than those of wrought materials.

Table XXI. Thermal Expansion of Cobalt-Base Heat-Resistant Castings

Alloy	Coefficient of Expansion, microinches per inch per °F					
	70 to 600 F	70 to 800 F	70 to 1000 F	70 to 1200 F	70 to 1500 F	70 to 1600 F
Stellite 21	7.83	7.96	8.18	8.38	8.68	...
61	7.64	7.96	8.18	8.48	9.24	...
6059	7.53	7.79	8.04	8.29	8.67	8.84
422-19	7.70	7.86	7.91	8.07	8.42	8.54
X-40	7.97	7.88	7.98	8.18	8.59	8.79

The actual wartime use of Stellite 21 alloy was primarily for the buckets in the General Electric Type "B" turbosupercharger for operation at 1500 F. This alloy, however, was also used in the blading for the turbines of jet engines

for operation at 1200 to 1350 F. At this lower temperature, the mechanical properties of wrought alloys, in general, are somewhat superior to those of cast alloys, but the ease of mass production by the precision casting method and the need for large quantities of blades of this type, resulted in a large percentage of such blading being produced as castings. A considerable proportion of this type of blading is still produced by these methods. Parts for stationary gas turbines, such as the blading for nozzle vanes operating up to 1800 F, were also cast from the Stellite 21 alloy because of its resistance to erosion and corrosion at high temperatures. Many other applications have been made that involve the heat resistance of these alloys, but for the most part these applications are of relatively small volume in comparison with the mass production of blades for gas turbines.

Table XXII. Thermal Conductivity of Cobalt-Base Heat-Resistant Castings

Alloy	Thermal Conductivity, watts per centimeter °C				
	200 C	300 C	400 C	500 C	600 C
Stellite 21	0.145	0.160	0.175	0.190	0.205
61	0.154	0.176	0.180	0.189	0.212
6059	0.141	0.155	0.166	0.181	0.198
422-19	....	....	....	....	....
X-40	0.148	0.175	0.183	0.194	0.219
SAE-4140	0.404	0.390	0.370	0.347	....

These cobalt-base alloys maintain their mechanical properties and resistance to creep at elevated temperatures by progressive aging in a temperature range from 1300 to 2100 F. Tests after aging show higher stress-rupture strengths and lower creep rates, but decreased ductility, in comparison with tests of the material in the as-cast condition. Numerous aged specimens were tested, since it was thought that the aged condition represented most typically the properties of the alloys in service, particularly after moderate service life. However, these alloys were not commonly used in the aged condition in fabrication and assembly, because slight upsetting in mechanical assembly or high stresses in welding require the greatest ductility possible in order to meet the assembly conditions best without trouble from cracking. The welding of Stellite 21 alloy to the high-alloy turbine wheels was carried out satisfactorily in production by manual arc methods and by automatic submerged-melt welding. However, the modifications of these alloys with high carbon contents offer greater difficulty during welding, because of cracks that may develop between buckets, cracks starting in the weld metal, and cracks in the bucket alloy itself, adjacent to the weld metal. The cobalt-base alloys are difficult to machine, because of the rapidity with which they work harden. Although the hardness of these alloys is usually less than Rockwell C 32, it is necessary to use tools tipped with sintered carbide to machine Stellite 21 alloy—the only one on which extensive machining operations have been performed satisfactorily on a production basis. Such operations usually result in increased hardness of the machined surface, as high as Rockwell C 40 to 45, and this hardness increases further as a result of exposure to temperatures from 1300 to 1600 F. Consequently, in blading

where machining operations are used, it is generally necessary to soften by annealing at 2100 F or higher to put the alloy in the best condition for assembly.

The microstructure of these alloys consists of a cobalt-rich matrix and three types of complex carbides. These carbides may be present separately or in the form of a eutectic, and in certain of the alloys during slow cooling a eutectoid forms, consisting of the cobalt-rich matrix and one form of carbide.

Precision castings of these alloys usually have a coarse grain size in comparison with wrought materials. This is considered desirable for good high-temperature properties, except where single grains may occupy the full cross section of highly stressed parts. It has been shown that very coarse grain size may result in wide variations in the value of the modulus of elasticity. Most of the results reported were from tests on precision-cast specimens ¼ in. in diam, although it has been found that there is no great difference between values of properties obtained from specimens ¼ in. and ½ in. in diam. At 1200 F the endurance properties of these cast alloys are somewhat inferior to those of the best wrought materials, but at 1500 F, the best wrought and cast materials have endurance properties of the same order of magnitude. It is likely that, when endurance

properties are determined at temperatures above 1500 F, the cast alloys will have an advantage at these higher temperatures.

The aging range of the cast cobalt-base alloys is somewhat higher than that of most wrought alloys; this is another reason for their satisfactory operation at the higher temperatures where the mechanical properties of wrought materials decrease more rapidly.

Chromium-Base Alloys. Recent research work[5] has indicated the interesting possibilities of chromium-base alloys for use at high temperature. Preliminary study of 13 binary and 9 ternary systems indicated that the Cr-Fe-W and the Cr-Fe-Mo alloys are the most promising. In later studies of the Cr-Fe-Mo alloys, it was found that the most useful combination of strength and ductility would not be far from the composition line in the Cr-Fe-Mo ternary diagram joining 60 Cr, 25 Fe, 15 Mo with 60 Cr, 15 Fe, 25 Mo. Between these two composition points, the properties appear to vary continuously, increasing in strength at 1600 F as the ratio of molybdenum content to iron content increases, and decreasing in ductility. The properties of these two alloys are summarized in Table XXVIII. These alloys must be both melted and cast in a vacuum.

The ductility of chromium-base alloys at high temperature increases with increasing purity and decreasing grain size. None of the alloys in the as-cast condition exhibited any measurable ductility in tension tests at room temperature. It is believed that further research on the alloys will result in an increase in their plasticity.

The Forging of Stainless Steel

By Waldemar Naujoks*

STAINLESS steels are considered to include, in a general grouping, the iron-base alloys designed to resist corrosion at normal temperatures and to resist deformation and scaling, as well as corrosion, at more elevated temperatures. All of the stainless steels have in common some basic properties in regard to forging and hot working. Compared with rates for carbon steels and low-alloy steels, the rate of heat transfer into stainless steels is slower, necessitating a longer period of heating for forging; stainless steels offer greater resistance to plastic deformation, which means that more blows or heavier blows are required to perform a given amount of forging. Though stainless steels have less tendency to scale during heating, any scale that is formed is usually of the hard variety, tending to cling tenaciously. These variations in characteristics from carbon and low-alloy forging steels may require a modification of normal forging practice, or may even require a considerable change in technique for the more difficult shapes. Stainless steels are classified in four general groups: (1) the ferritic or nonhardenable chromium steels, (2) the martensitic or hardenable chromium steels, (3) the austenitic or chromium-nickel steels and (4) the special heat-resisting alloys developed for high strength at high temperatures.

* Manager, Forged Valve Div., Ohio Injector Co., Wadsworth, Ohio

Prepared for the Subcommittee on Forging, with membership as follows: Adam Steever, *Chairman* (Columbia Tool Steel Company), W. W. Criley (The Ajax Manufacturing Co.), A. A. Handler (Deceased), G. R. Houghtaling (Rochester, N.Y.), Waldemar Naujoks (Ohio Injector Co.), William Telfer (University of Michigan) and R. W. Thompson (Transue & Williams Steel Forging Corporation).

General Working Properties. Many of the general considerations discussed in the article on "Heating Steel for Forging", page 348, apply to stainless steels. Stainless

Table I. Forging Temperatures for Ferritic Chromium Steels

AISI Type No.	Composition		Forging Temperatures, deg Fahr		
	Carbon, per cent	Chromium, per cent	Preheat	Initial Forging	Finish Forging

steels are sluggish in coming up to temperatures and require a longer soaking period to permit the heat to penetrate through the cross section of the bar or billet. Although preheating is not necessary for all types of stainless steels, it is desirable to preheat thoroughly to a temperature of about 1500 F, allowing sufficient time for uniform temperature to be attained through the piece. This should be followed by fairly rapid heating to the desired forging temperature. Sufficient soaking should be allowed at the preheating temperature, but should be minimized at the forging temperature.

Ferritic or Nonhardenable Chromium Steels. The ferritic chromium steels are forged more easily than the stainless steels in the other three groups but less easily than carbon steels. As indicated in Table I, the steels should be heated slowly to about 1400 F and should then be brought up fairly rapidly to 1900 F for small or medium forgings, and to not more than 2050 F for large pieces. These steels, highly susceptible to grain growth, must not be soaked at high temperatures. The first few blows should be light; then the piece should be worked rapidly at the initial forging temperature but more gradually as the temperature of the steel decreases. If reheating is necessary, the final reheating temperature should not exceed 1900 F. The finishing temperature should be about 1400 F for the best grain refinement. Although these steels do not harden appreciably during rapid cooling, it is desirable to anneal them to remove all forging and hot working strains.

Martensitic or Hardenable Chromium Steels. The martensitic chromium steels require careful heating for good results. As shown in Table II, the low-carbon grades should be heated slowly to about 1500 F, allowing sufficient time for heat to soak through the entire cross-sectional area. Then the steel should be brought up to a temperature of 2050 F for small and medium forgings and to not more than 2150 F for large pieces. The first few blows should be light, followed by more rapid working. In general, the forging practice used on carbon tool steel can be applied. For the higher-carbon grades, preheating is recommended, followed by a more rapid heating up to temperatures of 2000 to 2100 F. Care should be taken to avoid overheating and the finishing temperature should be approximately 1700 F. The work should be reheated if the temperature falls below 1700 F.

Austenitic Chromium-Nickel Steels. The austenitic chromium-nickel steels are forged with greater difficulty than are the straight chromium steels. As indicated in Table III, these steels should be heated slowly and carefully to about 1500 F, allowing sufficient time for the temperature to become uniform through the cross-sectional area; then the metal should be brought up to forging temperature by fairly rapid heating. The first few blows should be light, followed by more rapid working. In general, the forging practice used on carbon tool steel can be applied. Austenitic chromium-nickel steels should not be forged below 1700 F, since there is a tendency toward red shortness; if further forging is required, the metal should be reheated. Because the chromium-nickel austenitic steels have high strength at the higher temperatures, they require more blows or heavier blows than ordinary carbon steels.

Special Heat-Resisting Alloys. A number of highly alloyed heat-resisting alloys have been developed for applications involving high strength at elevated temperatures. These special alloys ordinarily require careful preheating and heating in furnaces designed to provide neutral atmospheres, or atmospheres that can be made slightly reducing or oxidizing for the particular grade of material. These alloys, having high strength at high temperatures, are forged with difficulty and require a special forging technique to prevent fiber rupture during forging.

Table III. Forging Temperatures for Austenitic Chromium-Nickel Steels

AISI Type No.	Composition			Forging Temperatures, deg Fahr		
	Carbon, per cent	Chromium, per cent	Nickel, per cent	Preheat	Initial Forging	Finish Forging

The Shaping and Joining of Stainless Steel

By V. W. Whitmer*

MANY TYPES of stainless alloys are available, having compositions to meet specific requirements, but nearly all of them can be grouped in two general classes, in regard to fabrication. The first class, containing chromium as an alloying element, with varying amounts of carbon for heat treating purposes, is generally known as the "straight chromium" or "ferritic" type and is magnetic. The second class, containing both chromium and nickel, with low carbon, does not respond to heat treating for hardening. It is known as the "chromium-nickel" or "austenitic" group and is nonmagnetic.

Excluding the higher-carbon alloys in the straight chromium group, the two most commonly used alloys in these groups are probably those containing 18% Cr with low carbon content, and the one containing 18% Cr and 8% Ni. In both groups are numerous other alloys, containing higher percentages of alloying elements chiefly for resistance to heat or corrosion, but these related alloys are worked much the same as the two mentioned above.

* Metallurgical Engineer, Republic Steel Corporation, Massillon, Ohio

Hence, in this article only these two alloys will be considered, with additional notes when necessary.

Piercing. For piercing, the straight chromium steels should be heated in the same manner as for forging. (*See* "Forging Stainless Steel", page 581.) A higher temperature will generally prove satisfactory. Although the 18% Cr alloy has been the most commonly used in the group, the steels containing 23 and 28% Cr have been pierced successfully.

For piercing, the chromium-nickel steels should be heated in the same manner as for forging the 18-8 alloy, but to a higher temperature. The 18-8 alloy is the most commonly used in the chomium-nickel group. The higher alloys, such as 25-12 and 25-20, have also been pierced successfully—the latter with considerable difficulty.

Welding. *18% Cr Stainless Steel.* This alloy can be welded satisfactorily by any commercial method except forge welding. For gas welding, a wire of the same composition as the steel is used with a slightly reducing flame. For arc welding, a coated electrode is used, protecting the metal going through the arc, from oxidation by the air. The coated electrode will also cover the deposited bead with a slag blanket, which stays molten and prevents loss of any chromium by oxidation. Because of the high temperature employed in welding, large grains will be developed, resulting in a brittle weld. At elevated temperatures, such as 400 F and higher, 18% Cr stainless steel is somewhat tough. However, the 18% Cr steel does not respond satisfactorily to subsequent heat treatment. For optimum results the chromium content should be 15 to 18% since it is possible to anneal after welding, thus producing fair ductility and bending properties.

The higher-chromium alloys behave in a similar manner, but the lower type, around 12% Cr, is suitable for heat treatment and can be annealed to show some ductility after welding. Additions of columbium, titanium or aluminum will reduce air hardening in the 12% Cr alloys. Such additions to the electrodes do not produce soft ductile weld metal; hence, if the welds are to be placed in service as welded, an austenitic electrode such as 18-8, 25-12 or 25-20 should be used, depending on the application. Such welds will be tough and ductile but they will have a higher coefficient of expansion than the straight chromium alloy.

18-8 Cr-Ni Steels. The chromium-nickel stainless steels are well adapted to welding and, like the others, can be welded by any commercial method except fire. Fire welding is not successful, because at the welding temperature a refractory film of oxide forms on the surface of the material; and this film, which will not dissolve or fuse with the commercial fluxes used today, acts as a separator when the pressure is applied on the two sections, thus preventing adhesion.

In gas welding, a rod of the same composition as the material being welded should be used with a slightly reducing flame, having about $\frac{1}{32}$ in. of acetylene feather on the end of the inner blue cone to prevent any possible oxidation of the chromium. If more acetylene is used, the weld may become carburized; if less acetylene is used, the chromium may be burned out. It is also advisable to apply a water paste of a suitable flux to the lower side of the joint, to protect this side from contact with the air.

The 18-8 alloy has a high coefficient of expansion—about 60% more than common steel; therefore it is necessary to hold the work in some manner while welding, in order to prevent the edges from moving away from each other. Because of the greater expansion, the joint should be held so as to produce as little buckling as possible when cooling. Gas welding is used chiefly on sections of 16 gage and lighter, although it can also be used on heavier sheets.

Electric-arc welding is probably the most common method used on stainless steel. A heavy flux-coated electrode of the same composition is necessary. This flux protects the molten metal from oxidation by the air, both while going through the arc and after being deposited. The flux should contain no material that would raise the carbon content of the weld metal, since this would reduce ductility as well as resistance to corrosion. Reverse polarity should be used; that is, the electrode should be positive and the work negative. The 18-8 alloy has a lower melting point than steel, as well as lower heat conductivity; therefore, less heat can be used and good penetration will be obtained in comparison with mild steel. A heavy bead or a series of heavy beads should not be deposited at one time, because the excessive contraction may cause cracks. Light beads should be deposited, about ⅛ in. or less in thickness. All 18-8 welds properly made on ⅛-in. plate will bend back flat on themselves in either direction without cracking.

Occasionally, columbium or titanium is added to 18-8 low-carbon steel, to prevent precipitation of carbide. This is not necessary for the low-carbon alloy in light plates, but is desirable in thicknesses greater than ⅝ in. or in material that will be used in service at temperatures in the carbide precipitation range from 1000 to 1500 F and under corrosive influences. Titanium in the welding electrode is not advantageous, since it is nearly all lost during welding. Columbium is more efficient and will be reduced less.

Atomic hydrogen welding is quite well suited to stainless steels and is frequently used in automatic operations. No flux is required, but the gas should be present on both sides of the weld in order to prevent any oxidation of the metal. If the edges fit closely, good joints can be obtained when little or no filler metal is added.

In the inert-gas shielded-arc process of welding, especially well adapted to stainless alloys, the molten metal is protected from contact with the air by a blanket of helium or argon, and oxidation is eliminated. This process is becoming more and more popular for automatic welding as well as for hand work, particularly on thinner sections.

Spot, seam and flash welding are satisfactory on 18-8 steel, but because of the characteristics of the alloy, a closer adjustment between current, time and upset is important. Automatic control is highly advisable when 18-8 steel is being welded. Less total heat will be required than with common steel sections of the same size.

The same procedure as for 18-8 steel should be employed in welding the higher chromium-nickel alloys. These alloys are usually subjected to high temperatures and the weld metal, as well as the plate or body, must withstand high-temperature service.

Soldering 18% Cr and 18-8 Cr-Ni Steels. Both types of stainless steels are soldered readily; the composition has no effect on the strength of the finished joint. If pickled sheets are employed, the ordinary zinc chloride or cut acid with commercial half-and-half solder will give fair results. However, stronger joints will be produced by use of special soldering fluxes for stainless steel. If the steel is polished, the edges should be roughened with a coarse file or abrasive cloth to obtain adhesion. A large soldering iron should be used with as low a temperature as possible, in order to keep any buckling at a minimum. When the joint has been completed, it should be washed with a solution of about 5% soda. Washing will neutralize any remaining acid, which, if not removed, will corrode the metal. If the joint is of such a nature that washing on both sides is impossible, it should first be tinned with a strong flux and washed; then it should be assembled and finish-soldered with a flux as nearly neutral as possible, so that if it is not removed, the steel will not corrode seriously.

Cold Forming Operations. *Cold Rolling 18% Cr Stainless Steel.* The straight chromium alloys can be cold rolled in sheet or strip, or drawn into wire in the same manner as common steel, except that lighter drafts, less speed and greater pressure are required. High surface finish can be obtained on cold rolled strip and very little polishing is required by an article made from this product. During cold working, the hardness will increase to about 187 to 241 Brinell (95 to 100 Rockwell B) but will seldom exceed this range. Annealing will reduce these values to about 140 to 160 Brinell (60 to 85 Rockwell B).

Cold Rolling 18-8 Cr-Ni Stainless Steel. The chromium-nickel grades can be cold rolled into strip or drawn into wire by methods similar to those employed for the straight chromium steels. Chromium-nickel grades will yield highly finished surfaces, but considerable hardening will result. Cold working will raise the hardness to about 400 Brinell (40 to 44 Rockwell C), with tensile strength as high as 250,000 to 300,000 psi.

Drawing 18% Cr Stainless Steel. This alloy has about two-thirds as much ductility as ordinary deep drawing

steel. Therefore, in stamping, the draw should generally be less for each operation. Under certain conditions it is possible to make two or more reductions without annealing the steel; however, it is usually advisable after each operation to anneal at 1450 F, and then to cool in air. A good drawing lubricant is necessary—one that will adhere to the work under greater pressure than is required for ordinary steel. Good adhesion and lubrication should be stressed rather than a heavy base. In the straight chromium group, the alloys containing more than 23% Cr will be less satisfactory for drawing than alloys in the lower chromium ranges. Reductions of 25 to 30% are common on the first draws, but subsequent reductions should be limited to approximately 15%.

Drawing 18-8 Cr-Ni Stainless Steel. Because of its high ductility, 18-8 stainless steel is used extensively in deep drawing work. This alloy has a much higher elongation, as measured by a tensile test, than extra deep drawing steel, showing about 45 to 50% as compared with 25 to 30% elongation in 8 in. for extra deep drawing steel. Also the Olsen and Erichsen test values are higher. However 18-8 stainless steel is subject to rapid hardening during cold working; hence as much work as possible should be performed in one operation. It is difficult to produce deep draws without annealing between operations, although at times two draws can be made without annealing. This annealing consists of heating at 1950 F, and cooling rapidly either in air or water.

A reduction of 40% or more can be made in the first operation, but subsequent reductions should be about 20%. If too much work is done at one time and the article is permitted to stand too long before annealing, it is likely to crack from excessive cold work. For this reason, if more than 40% reduction is made, the 18-8 stainless steel should be annealed at once. The presence of a flange will reduce this cracking tendency considerably. About twice as much clearance should be allowed as for ordinary steel.

Because of the high mechanical properties and stiffness of the 18-8 alloy, one-third more power will be required to produce a given draw. A lubricant with high adhesive qualities is necessary, capable of withstanding the high pressure without squeezing. All lubricants should be removed completely before annealing, because such materials are likely to injure the metal surface during the annealing operation. The dies for production work should have hard bronze inserts for the rings, and either bronze, steel or cast iron for the punch. The ring should be kept well polished, if possible, in the direction of drawing. Proper choice of lubricant should assist in reducing scoring and thus maintaining this polish.

Spinning 18% Cr Stainless Steel. The straight chromium alloys, especially those that contain 17% Cr or more, have not been particularly successful in spinning operations. Reductions are less, and more annealing is required than with the lower alloys. For best results in spinning, steel should be used that contains about 12 to 16% Cr.

Spinning 18-8 Cr-Ni Stainless Steel. The chromium-nickel type of steel has high ductility, and therefore is well suited to spinning operations, but because of rapid work hardening, this steel may require many annealing treatments. In order to reduce this hardening tendency, somewhat higher nickel content is employed (approximately 12% Ni) permitting about 2 to 3 times as much deformation before annealing. Ordinary tools of the solid round-nose type or roller type are used, though the roller type is preferred. A heavy-body grease or soap must be employed, keeping the surface well covered at all times to prevent scoring or abrading. All lubricants must be removed thoroughly before annealing, and if brass or copper alloy tools have been used, the work material must also be pickled in nitric acid to remove all traces of copper, since even small amounts of this metal will penetrate the sheet during annealing and will cause cracks during further spinning.

Machining. *18% Cr Stainless Steel.* This alloy machines a little differently from ordinary steel and more nearly resembles a 0.40 to 0.50% C steel. For best results, 18% Cr stainless steel should be in the cold worked or cold worked and annealed condition at the time of machining.

The 12% Cr steel, containing higher sulfur along with various other elements, is recommended for machine work. On a basis of 100% for screw stock, the product will rate approximately 90%. The 12% Cr alloy is used on automatic screw machines along with regular screw stock.

18-8 Cr-Ni Stainless Steel. This product is tough and difficult to machine. Best results are obtained with a slow cutting speed and moderately heavy cuts. Tools must be kept sharp, because any dragging may work harden the product and will increase the difficulty. Drills should be ground flatter than usual to produce less wedge effect and the speed should be reduced to about one-half that used for drilling steel. Center punch marks should be as small as possible in order to reduce the effect of cold working.

For drilling or cutting, a good grade of sulfur-base oil should be used. In sawing, a high-speed blade should be used, of the fine-tooth wavy type. A circular saw is preferred whenever possible.

Selenium additions to 18-8 will improve the machining properties sufficiently to compensate for a slight sacrifice of resistance to corrosion.

Grinding, Polishing and Buffing. Both types of stainless steel, if only rough ground with a coarse wheel, will discolor when subjected to a salt spray. However, if a higher finish is applied, no rusting will occur on the 18% or higher Cr steels or on any of the chromium-nickel steels.

Rough grinding should be done with 80-grit, set up with glue and abrasive on a cotton wheel. This should be followed by 100-grit used on a greased wheel surface, then with a succession of fine wheels, such as 120, 150, 180, 200 and 240-grit, depending on the finish desired. Grit as high as 180 should be of the manufactured type, low in iron. Higher than 180, Turkish emery will give best results.

For a higher finish, 240-grit should be used with grease and then buffed with a stainless steel buffing compound on a cotton buff. This operation should be followed with a few passes, using green chromium oxide grease stick for final color. These stainless steels should not be buffed with chromium oxide, because drag pits may develop.

For cutting, a speed of 5000 to 6000 ft per min should be used, and for buffing, 6000 to 8000 ft per min.

Cleaning, Pickling and Electrolytic Polishing of Stainless Steel

By H. A. Grove*

THE REMOVAL of scale from stainless steel is described here under the headings Blast Cleaning and Pickling. The removal of lubricants, grease, drawing compounds and miscellaneous contamination, from finished or semifinished articles, is discussed under Cleaning. Information is included also concerning the electrolytic polishing and passivation of stainless steel.

Cleaning. In many fabricating operations, it is necessary or desirable to employ a lubricant that will prevent excessive scratching, especially where high finishes are concerned. Under such conditions and even when dry forming is involved, the accumulated deposit must be removed from the surface before the equipment is shipped.

If the lubricant or deposit has a grease base, it is best to wash the metal first with a good solvent, such as kerosene, gasoline, naphtha or the like, and wipe dry. Although this method of cleaning removes all the grease, a thin, oily surface film will remain, which can be absorbed by finely bolted whiting. The whiting (precipitated calcium carbonate) should be sifted onto the surface and wiped off

* Republic Steel Corporation, Massillon, Ohio

with a soft cloth, such as flannel. This will bring out the true luster of the metal.

Caustic cleaners are also employed for removing drawing compounds or lubricants. After passing through the caustic cleaning solution, the stainless steel part should be washed in hot water and dried, either by a blast of dry air or by wiping with a soft cloth.

When the stainless steel is to be used for architectural trim—either interior or exterior—it may become spotted, during the building period, by materials such as cement, dust, paint and lacquer. The steel can be covered with a heavy paper applied with paper hanger's paste, which can be washed off later with warm water. If the surface is not protected in this manner, it should first be washed with benzene, benzol, turpentine, paint remover, or a similar solvent, depending on the deposit in question. To remove heavy dirt or other such substances, steel wool should never be used; neither should a metal scraper, or any other mechanical device, because scratching and contamination of the surface are almost certain to result. Steel or iron particles may thus become embedded in the surface and later may rust, discoloring the stainless steel and making it appear as though it were rusting, although it has not been affected.

This preliminary cleaning should be followed by a final washing, using half and half whiting and 00 pumice on a soft rag that is wet with either tap water or water to which a little ammonia has been added. The metal should always be rubbed in the direction of the polishing lines, never with a circular or cross-the-grain motion, since light scratches or light and dark areas may result. The excess of powder should be removed with a clean wet cloth and the remainder should be allowed to dry. Then the steel is wiped with a soft dry cloth, such as canton flannel.

The above procedure will be satisfactory for No. 4 or No. ▮ finishes.* If a No. 7 or No. 8 finish is to be cleaned, pumice should not be used, because it will scratch. Ammonia water and whiting should be used, or better still, dry whiting alone.

The whiting and 00 pumice can be obtained at any hardware or paint supply house. The whiting should be of the best grade, finely bolted and free from all grit and foreign substances.

Blast Cleaning. Blast cleaning of stainless and heat-resisting steels is usually done on semifinished products, though it may be used as a final cleaning operation. In such instances the process should always be followed by a passivation treatment to remove any iron contamination.

Blast cleaning may be done by sandblasting, grit-blasting, or vapor-blasting. The sand for sandblasting should be a good grade of silica sand and as low in iron content as possible. The size of the particles is determined largely by the type of work to be done.

In grit-blasting, the grit is generally made from high-alloy material and is used in the form of sharp particles. Here again the size of the particles and the air pressures used will be governed principally by the work to be done. In the grit-blasting of sheets and plates, care should be taken not to use too heavy a grit or too much air pressure, since the plate may become warped as a result of the grit cold working the surface.

Vapor-blasting or liquid-blasting consists in cleaning the surface with a fine abrasive carried in a liquid blast. The size of the abrasive material, which may vary from 100 to 2500-mesh, is controlled, in this instance too, by the type of surface desired on the work.

Pickling. Pickling is the treating of steel with an acid, salt or base, in such a way as to remove the scale or oxide formed during a heating operation.

The most common method for pickling stainless steel, uses acid solutions and is ordinarily divided into two operations or steps. The first operation consists in immersing the steel in a solution of 8 to 12% (by volume) of sulfuric acid at 150 to 170 F for 10 to 30 min. The time is governed by the type of scale or by the alloy being pickled. A suitable inhibitor is ordinarily used with this solution. Another acid bath that may be used in this primary pickle is ■ solution of 10 to 15% (by volume) of hydrochloric (muriatic) acid at 130 to 140 F. A suitable inhibitor should be used with this solution also. After pickling in either the sulfuric or the hydrochloric acid solution, the stainless steel should be washed thoroughly.

In the second operation or the step after pickling in the above solutions, the steel is immersed in a solution of 10 to 15% (by volume) of nitric acid plus 1 to 2% (by volume) of hydrofluoric acid at 120 to 130 F for 10 to 20 min. The time will be governed by the alloy and the nature of the scale. The stainless steel should then be washed, preferably with hot water, to remove all acid, and should be dried rapidly to give the best surface appearance.

The above solutions are suitable for batch pickling. Wooden tanks are suitable for all the acid solutions mentioned above. Ceramic or lead-lined tanks can be used for sulfuric acid and a rubber lining can be used with hydrochloric acid.

A method widely employed in strip mills that roll stainless steels is a continuous electrolytic pickle, using different acid solutions. The customary pickling line consists of two or more tubs, containing either a solution of 6 to 10% (by volume) of nitric acid or a solution of 4 to 8% (by volume) of sulfuric acid. The current is generally induced into the strip by proper placing of the electrodes. For pickling straight-chromium steels, either of these acid solutions may be used; but for the chromium-nickel grades, it may be necessary to have a final tank, containing a solution of 10 to 15% of nitric acid plus 1 to 2% of hydrofluoric acid at 110 to 120 F. This solution is not used electrolytically. After passing through the pickling tanks, the strip is washed and dried. Methods of descaling are summarized in Table I.

Table I. Methods for Descaling Stainless Steel in Acid Solutions

Acid	Rinse	Acid	Rinse
Sulfuric, 8–12% by vol 150–170 F, 10–20 min Use inhibitor	Water	Nitric, 10–15% by vol Hydrofluoric, 1–2% by vol 120–140 F, 10–15 min	Water
Hydrochloric (Muriatic), 10–15% by vol 130–150 F, 10–20 min Use inhibitor	Water	Nitric, 10–15% by vol Hydrofluoric, 1–2% by vol 120–140 F, 10–15 min	Water
Sulfuric, 8–12% by vol Sodium chloride, 2–4% by wt 150–170 F, 10–20 min Use inhibitor	Water	Nitric, 10–15% by vol Hydrofluoric, 1–2% by vol 120–140 F, 10–15 min	Water
Sulfuric, 8–12% by vol Ferric sulfate, 5% by wt 150–170 F, 15–20 min	Water	Nitric, 10–15% by vol Hydrofluoric, 1–2% by vol 120–140 F, 10–15 min	Water
Sulfuric, 8–12% by vol 150–170 F, 10–20 min Use inhibitor	Water	Ferric sulfate, 6–10% by wt Hydrofluoric, 1–2% by vol 120–140 F, 10–15 min	Water
Sulfuric, 4% by vol Hydrochloric (Muriatic), 4% by vol 150–170 F, 10–20 min Use inhibitor	Water	Nitric, 10–15% by vol Hydrofluoric, 1–2% by vol 120–140 F, 10–15 min	Water
.....	.....	Nitric, 10–15% by vol Hydrofluoric, 2% by vol Hydrochloric, 2% by vol 120–140 F, 10–20 min	Water

Pickling of Stainless Steel in Solutions That Contain Ferric Sulfate. For the austenitic stainless steels, a mixture of approximately 10% (by weight) of ferric sulfate and 1 to 2% (by volume) of hydrofluoric acid may be used at a temperature of 120 to 140 F. For the straight-chromium steels this same solution may be used, but these steels should first be pickled in sulfuric acid, using an 8 to 10% (by volume) solution at 150 to 170 F. Another suggested method is to add ferric sulfate (approximately 5 to 10% by weight) to an 8 to 12% sulfuric acid solution and use at 150 to 170 F. This treatment should be followed by a dip in a solution of nitric acid (10 to 15% by volume) and hydrofluoric acid (1 to 2% by volume) at 120 to 140 F. Inhibitors are not needed with these acid mixtures. Solutions that contain ferric sulfate may also be used as a clean-up pickle, after the steel has been descaled in molten caustic.

* A No. 4 finish is a bright ground or grit-finished surface. No. 6 finish is similar to No. 4 but has been dulled to a "satin" finish. Both No. 7 and No. 8 are buffed finishes; No. 8 has a higher luster than No. 7.

Table II. Methods for Descaling Stainless Steel in Salt Baths

Salt	Rinse	Acid	Rinse	Acid	Rinse
Sodium hydroxide, 60 to 90% by wt Sodium nitrate, 10 to 40% by wt 900 to 1000 F, 5 to 15 min	Water Quench	Sulfuric or Hydrochloric (Muriatic), 8 to 12% by vol Inhibitor 150 to 170 F, 3 to 5 min	Water	Nitric, 5 to 10% by vol Hydrofluoric, 1% by vol 120 to 140 F, 5 to 10 min	.....
Sodium hydroxide, 98% by wt Sodium hydride, 2% by wt 750 to 850 F, 5 to 15 min	Water Quench	Sulfuric, 8 to 12% by vol Inhibitor 150 to 170 F, 1 to 3 min	Water	Nitric, 5 to 10% by vol Hydrofluoric, 1% by vol 120 to 140 F, 5 to 10 min	Water

Sodium Hydroxide–Sodium Hydride Process. This method of descaling employs a bath of molten salt composed of approximately 98% (by weight) sodium hydroxide and 2% (by weight) sodium hydride, at 750 to 800 F. The work material is immersed in this bath for 5 to 15 min, depending on the nature and amount of scale. The steel is then rinsed in water and dipped for 1 to 2 min in a 10% (by volume) sulfuric acid bath at 160 to 180 F. An inhibitor is used with the acid. The steel is again rinsed.

The final operation in this descaling process is a 5 to 10-min pickle in a solution of 7% (by weight) nitric acid and 1% (by weight) hydrofluoric acid at 150 to 170 F. The steel is then rinsed in water.

Other Salt Bath Processes. Another salt bath for descaling stainless steels consists essentially of caustic soda. The bath is operated at 900 to 1000 F; the material to be cleaned is immersed for 2 to 15 min, depending on the quantity of scale on the work, and is then washed in water and dipped in weak hydrochloric or sulfuric acid for 30 to 60 sec. Optionally an additional momentary brightening dip in weak nitric or nitric-hydrofluoric acid is used to obtain higher finish and passivation. Methods of descaling in salt baths are summarized in Table II.

Passivating. Passivating is the treating of the surface of stainless steel with certain acid or acid salt solutions to remove contaminating iron particles and to produce a passive film on the steel surface.

In forming operations, such as machining, bending, drawing and rolling, where the stainless steel is in close contact with steel dies and is probably abraded by them, some iron may become embedded in the stainless steel surface. These particles may rust, causing a discoloration of the stainless material. To remove iron particles and any other foreign substances, the stainless steel parts are dipped into one of the following solutions. For the straight chromium type of stainless steels, a solution of 50 to 70% nitric acid (by volume) is very satisfactory at 130 F for 15 to 30 min. Another good passivating agent for chromium steel is a mixture of about 20% nitric acid (by weight) and 2% sodium dichromate, at 110 to 120 F for 15 to 30 min.

The chromium-nickel stainless steels can be passivated in a 25% nitric acid solution at 120 F for 20 to 30 min, or the nitric acid–dichromate solution mentioned before may be used. After any immersion in the passivating solution, stainless steel parts should be washed in water and dried. If the product is to be polished, the passivation treatment need not be used, since grinding and polishing will remove any particles of iron. However, for exposure outdoors, a final passivation treatment is advisable.

Electrolytic Polishing of Stainless Steel. The polishing of stainless steel by electrolytic methods has become industrially important. This method of polishing has been known for some time, but until recent years was used only as a laboratory method for polishing specimens.

In electrolytic polishing, the work piece is the anode, which is immersed in an electrolytic bath that can form a soluble salt with the metal. The cathode can be made of stainless steel, lead, graphite or other conductive, inactive material. If the part to be polished is of irregular shape, it may be necessary to have a cathode of the same general shape or of a shape that will produce a uniform smoothness on the part.

The current density may vary from a few tenths of an ampere to 30 amp per sq in. Unless sufficient current density is used, an etched or frosted appearance results.

The solutions used for electrolytic polishing are, for the most part, of two classes. The first group of solutions contains phosphoric or sulfuric acid or both, to which may be added such acids or other chemicals as tartaric, citric or chromic acid, alcohol, glycerol, benzoic acid, benzene, commercial inhibitors, and the like. These solutions have low electrical resistance and operate on low voltages, usually not higher than 25 v. The operating temperature of these solutions is about 150 to 300 F, depending on the solution. Higher temperatures require higher current density.

The second type of solution that is employed, is based on perchloric acid, to which may be added acetic acid, acetic anhydride, alcohol and ether. These solutions operate best on voltages of 28 to 45 v. Since the current input will raise the temperature of these solutions, it is necessary to cool them, for they should be operated at temperatures around 85 to 90 F.

The perchloric acid solutions can be operated safely around 85 F. They should not be allowed to become hot and consequently hazardous. Incidental organic compounds should be kept from entering the bath, because they may form explosive mixtures with the perchloric acid. These solutions are a little more expensive, which may account for a wider adoption of the phosphoric and the sulfuric acid solutions.

The article to be polished should be totally immersed, since foaming of the solution may result in poor polishing; also attack may be severe at the interface line between solution and air. The space between the part and the cathode may vary from ½ to 6 in. A good surface is a prerequisite for a good polished finish. Agitation of the solutions is not necessary, but it will reduce any tendency to streak and will increase the efficiency of the anode. If agitation is used, it should be mild, because the greatest solution of metal is where the turbulence is greatest. For flat surfaces, agitation is not recommended. Large surfaces such as sheets are less readily polished than bars, wire and small formed articles and may look hazy or pitted.

Before this method of polishing is adopted, a careful study should be made of the costs as compared with those for other standard mechanical methods of finishing. There are also other factors, such as size and shape of work material, which may encourage the use of one method of polishing in preference to another.

Magnetically Soft Materials

BY T. D. YENSEN*

SEVERAL conflicting characteristics are often required in magnetically soft materials. For this reason a number of different magnetic alloys have been developed, ranging from pure iron through the silicon irons and high-nickel iron alloys to cobalt-iron alloys.

The following characteristics are important: (1) Hysteresis loss arising from internal magnetic "friction" during a magnetic cycle. This loss should be low. (2) Eddy current loss resulting from electric currents induced in the material by changes in flux. This loss should be low. (3) Magnetic permeability should be high, and sometimes must be high or constant at low field strengths. (4) Saturation value should be as high as other considerations permit. (5) In special applications a definite change in permeability with temperature is required. (6) The cost, availability and ease of processing are important, and frequently determining, factors.

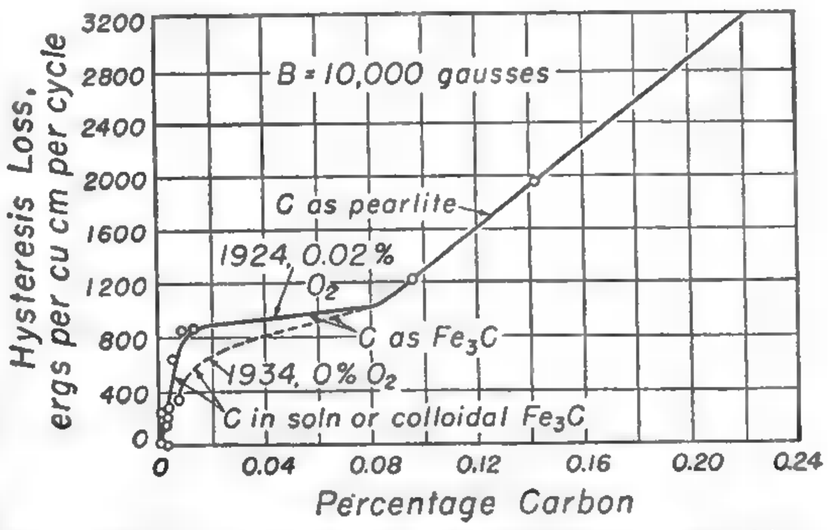

Fig. 1 Effect of carbon content on the hysteresis loss of iron

Effect of Impurities.[1] Since the ferromagnetic properties of metals depend on the regularity of the crystal structure, it follows that anything affecting this regularity will also affect the magnetic properties. Impurities like carbon, sulfur, nitrogen and oxygen are particularly harmful because, in solution, they occupy interstitial spaces in the crystal structure and very small amounts therefore produce large effects.[1] Furthermore, since the solubility is low at room temperature, the excess solute is slowly precipitated in the form of small particles inside the grains, with an even greater disturbing effect usually referred to as "aging". In iron and iron-silicon alloys, the carbon content especially should be kept low in order to obtain low hysteresis loss and high maximum permeability. The carbon content should not be greater than 0.01% and preferably should be less than 0.005%. Figure 1 shows the effect of carbon content on the hysteresis loss of iron. Sulfur and oxygen likewise should be held down to similar values.

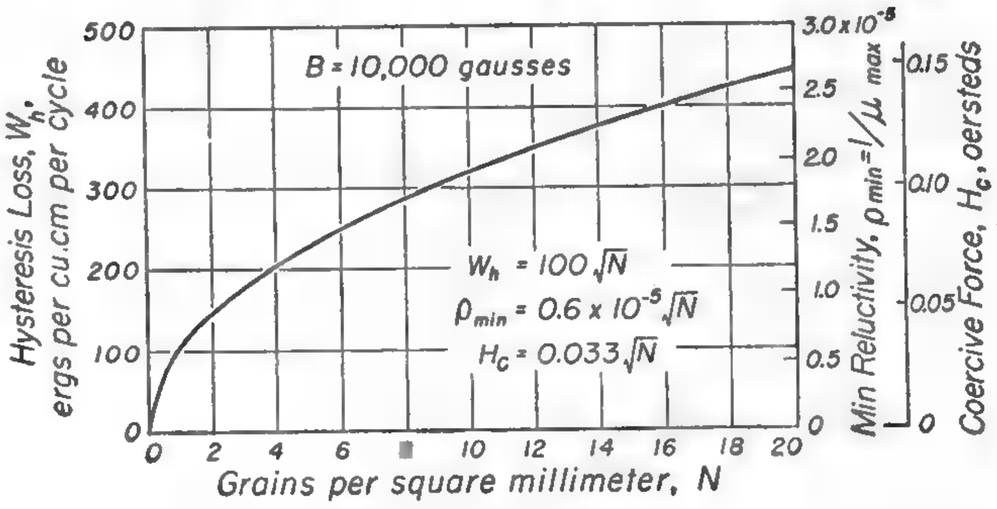

Fig. 2 Net effect of grain size on the hysteresis loss of pure iron

Effect of Grain Size.[1] Because of the disturbances at the grain boundaries, the fewer the grain boundaries the better are the magnetic properties, which is another way of saying that the grain size should be as large as possible with the single crystal as the limit (Fig. 2).

Effect of Grain Orientation. Almost all ferromagnetic materials are magnetically anisotropic; that is, they have different magnetic properties in the different crystallographic directions. This is shown in Fig. 3 for iron[2] in which the direction parallel to a cube edge [100] is the

* Manager, Magnetic Department, Westinghouse Research Laboratories, East Pittsburgh, Pa.

one having the highest permeability. Other metals are different in this respect. For example, in nickel the direction of easy magnetization is that of the cube diagonal [111]. In all instances, crystallographic orientation should be taken into account in controlling the magnetic properties of ferromagnetic materials.

Effect of Alloying Elements. Although pure iron is, in many respects, the ideal ferromagnetic material, it has certain drawbacks that make it unsuitable for practical use, especially in a-c circuits. The resistivity is low, which necessitates rolling the iron very thin to reduce eddy

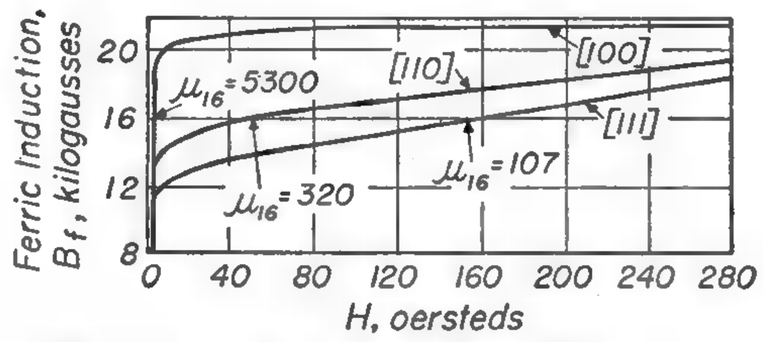

Fig. 3 Effect of grain orientation on the *B-H* properties of iron (Honda and Kaya)

currents, and when this is done, the magnetic properties are poor. Therefore one of the main objects of adding alloying elements is to increase the electrical resistivity of iron so as to make the metal useful in a-c circuits—which means perhaps 75% of all applications of magnetic materials in industry. Figure 4 shows how the various elements affect the resistivity of iron. Except for carbon in solution, silicon and aluminum increase the resistivity more than any other elements.

Silicon and aluminum also have another important effect; they eliminate the allotropic transformations in iron, so that the alloys can be annealed at high temperatures without recrystallization during cooling; thus large grains can be obtained. Both silicon and aluminum are substitution elements and for this reason can be added to iron in

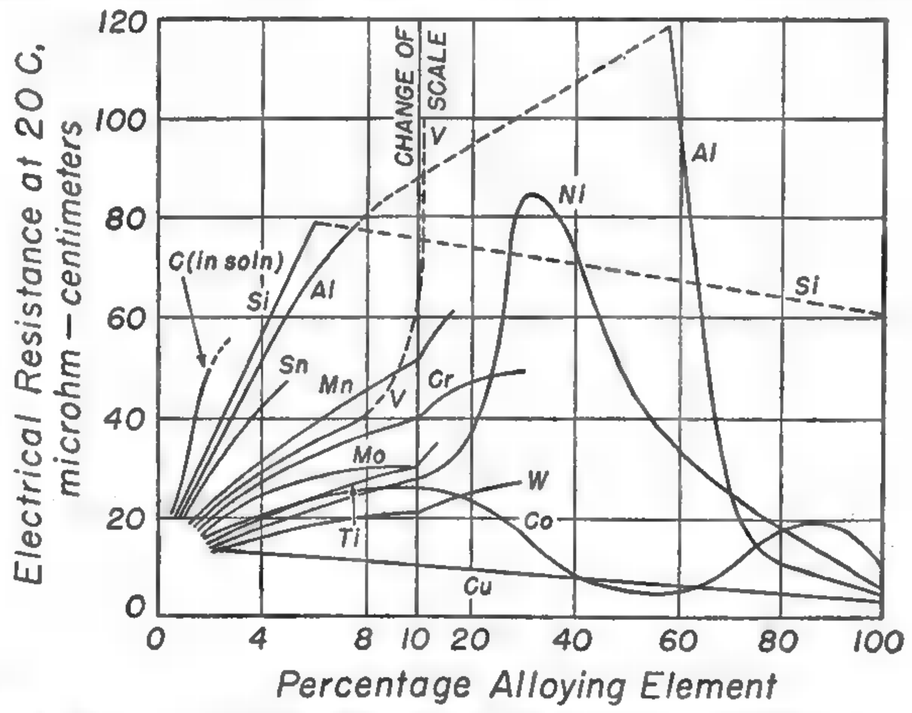

Fig. 4 Effect of alloying elements on the electrical resistance of iron (Stäblein, Yensen)

fairly large quantities without affecting seriously the magnetic properties, although such additions do reduce the saturation value (Fig. 5). More than 4.5% Si or 8% Al makes iron too brittle for most commercial use.

The chief difficulty in connection with silicon and aluminum is that they form stable oxides, so that if the iron is not thoroughly deoxidized before the alloying elements are added, oxide inclusions are formed that cannot again be eliminated, and these have deleterious effects on the magnetic properties. Aluminum is particularly undesirable in this respect.

Valuable magnetic properties are obtained by combining iron with nickel or cobalt, or with both, and by adding to these combinations other elements, such as copper, vanadium, molybdenum or chromium, as will be seen later.

Magnetic Materials. *Iron.* By careful preparation of a single crystal of iron, Cioffi[4] has obtained a maximum permeability of 1,430,000 and Ziegler and Yensen[5] have prepared ring samples of iron, having a hysteresis loss of 70 ergs per cu cm per cycle for $B = 10{,}000$.

For experimental uses, iron can now be obtained with

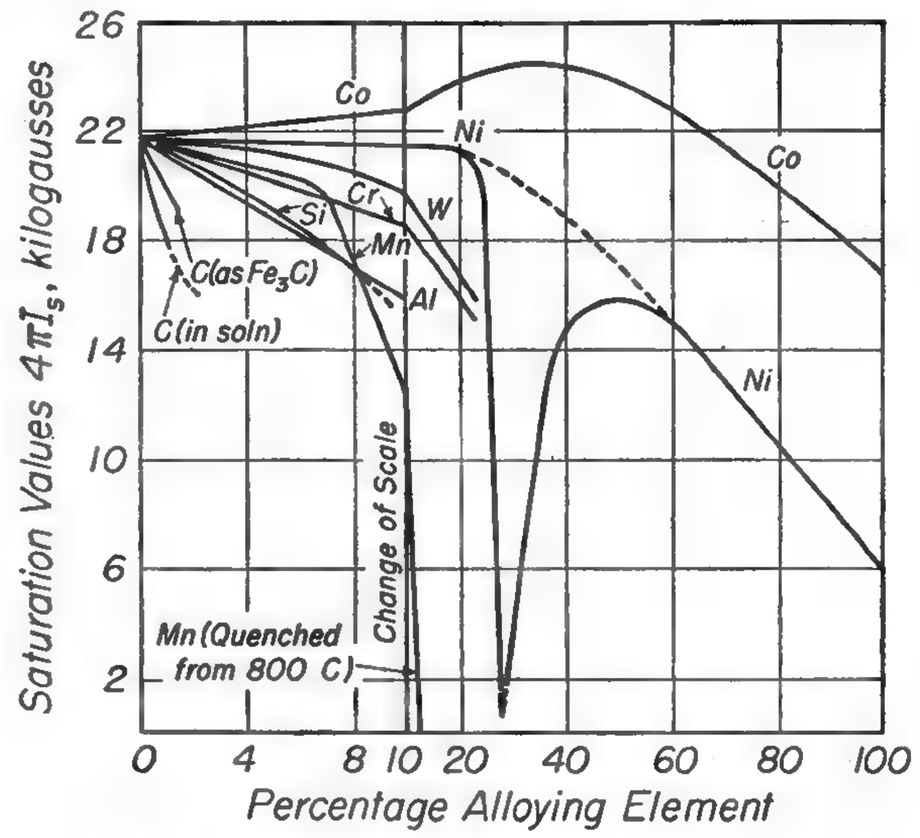

Fig. 5 Effect of alloying elements on the saturation value of iron (Stäblein, Yensen)

a purity of 99.95% or more, having magnetic properties as shown in Fig. 6; maximum permeability of about 100,000 and a hysteresis loss for $B = 10{,}000$ of about 100 ergs per cu cm per cycle (Puron).

The latest saturation value of iron comes from the Physikalisch-Technische Reichsanstalt[6] and is given as:

$4\pi I_s = 21{,}580 \pm 10$ gausses based on a density of 7.878

These values agree well with those given by Cleaves

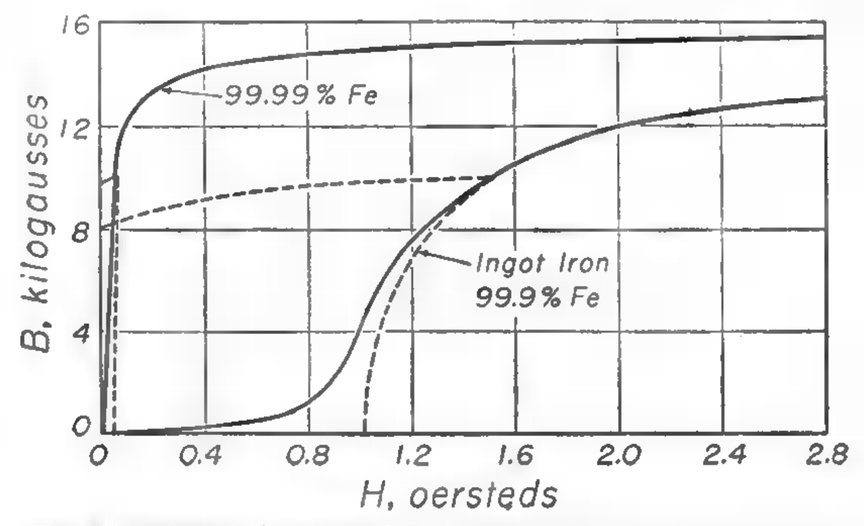

Fig. 6 Hysteresis loops and *B-H* curves for nearly pure iron

and Thompson.[7] The electrical resistivity given by Cleaves and Thompson as the most reliable value is 9.8 microhm-cm at 20 C with temperature coefficient 0.0065 per °C.

Iron-Silicon Alloys. Although pure iron is in many respects an ideal magnetic material, it is easier to obtain good magnetic properties in iron by the use of a small amount of silicon than without it.[8] Brittleness imparted by the silicon limits the amount in practice to about 4.5%, although 6% may be used for special purposes.*

The commercial grades of silicon iron in common use are made in basic open hearth or electric furnaces. These alloys contain from 0.5 to 4.5% Si. Sheets are usually hot rolled from ⅝-in. sheet bars to gages from No. 20 (0.0375 in.) to No. 30 (0.0125 in.). The finished hot rolled sheets may be up to 48 in. wide and of lengths usually in multiples of the widths but not much more than 120 in. long. After being pickled to remove scale, the sheets are cold rolled slightly to ensure satisfactory flatness. They are

* For thermal, electrical and mechanical properties of these alloys, see "Silicon in Steel", page 476.

Table I. Magnetic Properties of Standard Electrical Sheet

Grade	Uses	% Si	Sat. Value, $4\pi I_s$	Min Flux Density for $H = 10$	Max Losses (watts per lb[a]) for 60 cycles, $B = 10{,}000$: 0.014 in. 29 gage	0.019 in. 26 gage	0.025 in. 24 gage	$B = 15{,}000$: 0.014 in. 29 gage	0.019 in. 26 gage	0.025 in. 24 gage	Max Aging Factor, %

(a) To obtain watts per kilogram, multiply by 2.2.

then coated with a refractory and annealed in stacks at a high temperature, in either electrically heated or gas-heated furnaces, and are slowly cooled, after which a certain representative portion (about 0.1%) of the sheets from each anneal are sheared into Epstein strips 3 by 50 cm and are tested for energy losses and permeability. The lots are then graded on the basis of these results. Table I shows the properties of the grades used in this country, tested in accordance with ASTM Specification A 34.

Although most silicon irons are still hot rolled into sheets, there is a tendency, particularly for the alloys of lower silicon content, to change to cold rolling. After being hot rolled to a thickness of about 0.1 in., the strip is pickled and is then cold rolled to the final thickness. For the subsequent anneal, the metal is either passed slowly through a continuous furnace or is cut into sheets for stack annealing, as described for hot rolled sheets.

The properties shown in Table I are for standard Epstein samples cut 50% with and 50% across the rolling direction of annealed sheets, and without being annealed to remove shearing strains. If the sheet is used altogether in the rolling direction, the above losses may be 10%

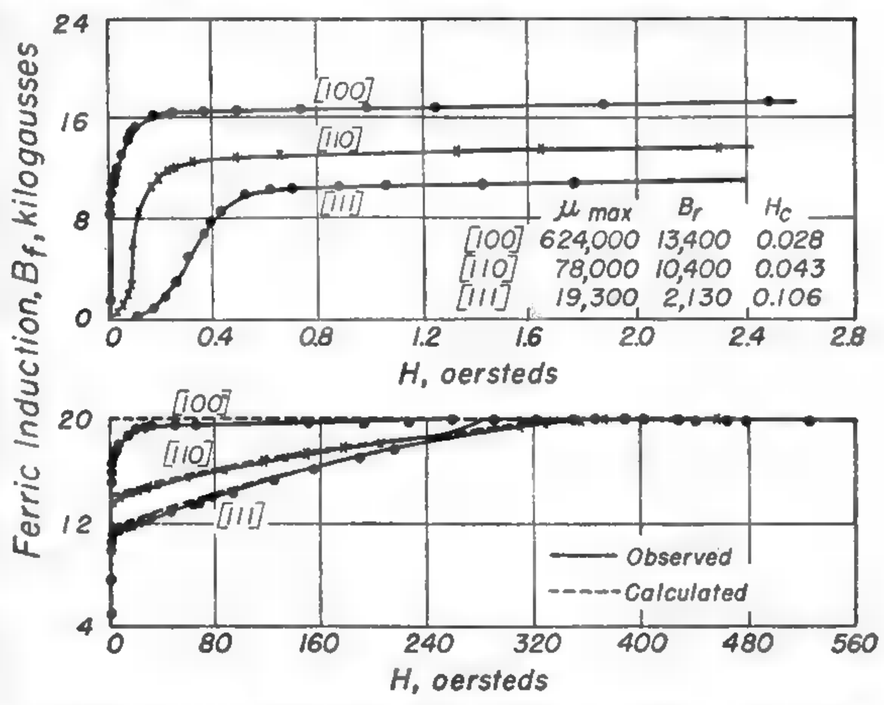

Fig. 7 Observed and calculated *B-H* curves for [100], [110] and [111] directions in single crystals of 3.85% Si iron (Williams)

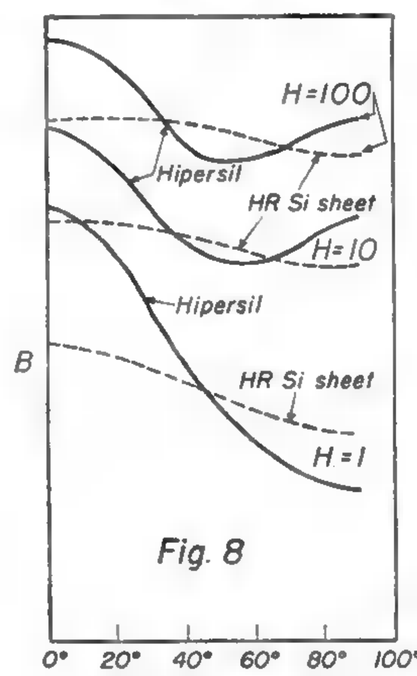
lower, and if the sheared punchings are reannealed, the losses may be lowered by 10%, so that 0.014-in. Transformer III grade, tested in the rolling direction after reannealing, should have a loss for $B = 10{,}000$ of 0.48 watts per lb, or less.

After annealing, the impurities in the above high-grade materials may be as follows: <0.03% C, <0.02% S, <0.02% P, <0.10% Mn. Of these impurities carbon is the most injurious (Fig. 1), and constant efforts have been made to lower the carbon content, as well as the sulfur content.

Grain size in silicon iron is just as important as in iron (Fig. 2) as far as losses and low-density permeability are concerned, but the crystallographic orientation is equally important and is the determining factor with regard to high-density permeability. Like iron, iron-silicon alloys are more easily magnetized in the direction of the cube edge, [100], than in any other direction,[3] as shown in Fig. 7, and methods have been developed during the past ten years for rolling and heat treating iron-silicon alloys so as to obtain most of the grains with a cube edge parallel to the direction of rolling.[9] By this means a flux density is obtainable for $H = 10$, of the order of 30% higher than for hot rolled sheet.

By a combination of the above rolling process with a refining annealing process, it is possible to obtain all-round improved magnetic properties, with the material magnetized in the direction of rolling. The alloy has been designated "Hipersil" and is used exclusively for transformer cores.[10] It contains between 3 and 3.5% Si.

For Hipersil in comparison with the best hot rolled sheet, Fig. 8 shows the variation in flux density with orientation for various values of magnetizing force, and Fig. 9 shows the variation in losses with orientation. These figures indicate clearly the advantage obtainable when such oriented material is used, and also the necessity for using it in the rolling direction. For this reason Hipersil cores are preferably made by coiling the strip on mandrels, welding the ends, annealing the cores, impregnating them, cutting them in two and polishing the



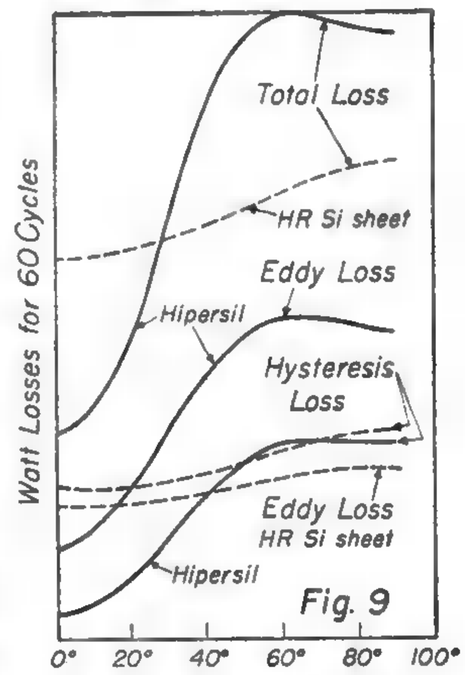


Fig. 8 Comparative flux densities for Hipersil and the best hot rolled sheet as a function of orientation

Fig. 9 Comparative watt losses at 60 cycles for Hipersil and the best hot rolled sheet as a function of orientation

joints to make them as nearly perfect as possible. In this way the transformers are easily assembled and taken apart for repairs, if necessary. Large Hipersil transformers, however, are still made by stacking plates, cut so as to have the flux parallel to the direction of rolling, but in such a way as to have the joints staggered in adjacent layers.

Figures 10, 11 and 12 show curves of B versus H, hysteresis loops and watt-loss curves for Hipersil in comparison with hot rolled 4.25% Si irons, both materials tested in the direction of rolling. It is clear from these curves that by the use of such oriented materials as Hipersil, a flux density can be used 25 to 30% higher than is practical with hot rolled sheet, thus effecting a saving not only in core material but also in copper, oil and tank.

High-grade transformer sheet and strip does not age as received from the makers (*see* Table I); that is, the losses do not increase with time at operating temperatures. But this does not mean that silicon iron is inherently nonaging. Unless the steel manufacturer follows the correct heat treating practice, silicon iron may age considerably under operating conditions.*

Iron-Aluminum and Iron-Aluminum-Silicon Alloys. Although aluminum is known to have an effect on iron

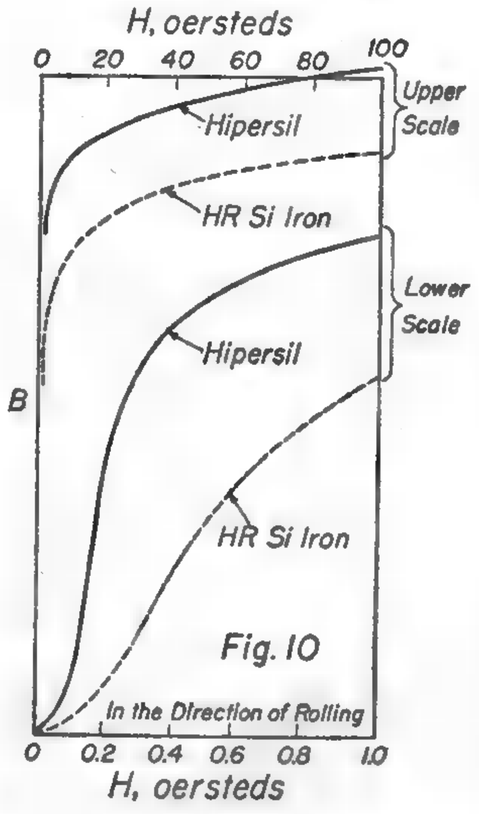

Fig. 10

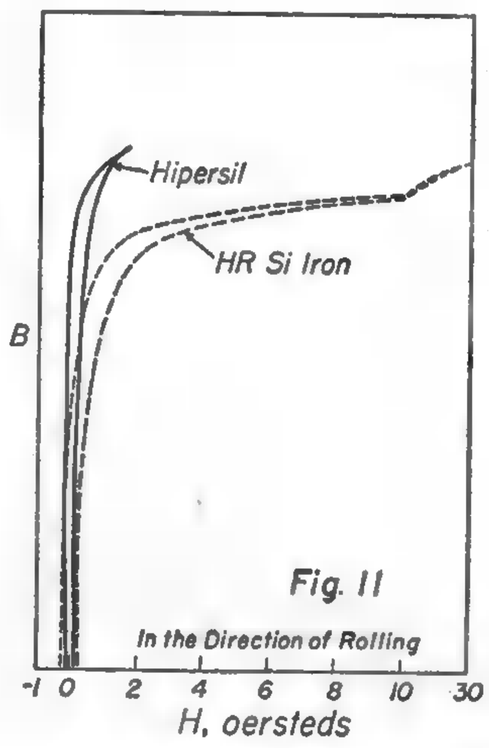

Fig. 11

Fig. 10 Comparative *B-H* curves for Hipersil and the best hot rolled sheet in the direction of rolling

Fig. 11 Comparative hysteresis loops for Hipersil and the best hot rolled sheet in the direction of rolling

somewhat the same as the effect of silicon, both as to electrical resistivity and as to magnetic properties,[11] aluminum has never become a serious competitor on account of the difficulties in the manufacturing processes. Ternary alloys of Fe-Si-Al have been investigated by Masumoto.[12] The alloy containing 8 to 11% Si and 5 to 6.5% Al is reported to have an initial permeability up to 35,000, a maximum permeability up to 162,000 and a hysteresis loss down to 28 ergs for $B = 5000$. With such high silicon and aluminum contents the saturation value is necessarily low ($4\pi I_s = 11{,}000$). The alloys are brittle.

This alloy has been suggested for loading coils, but, in the form of compressed cores, it would have to meet severe requirements for hysteresis and permeability, in

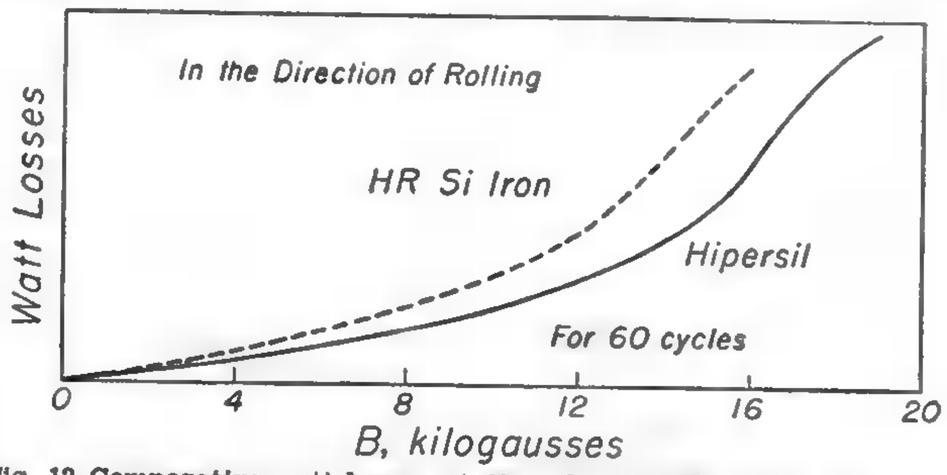

Fig. 12 Comparative watt losses, at 60 cycles, for Hipersil and the best hot rolled sheet in the direction of rolling

order to offer advantages over the powdered iron-nickel alloy now used in the United States.

Iron-Nickel Alloys. In the preparation of this section, liberal use has been made of Data Sheet No. 2, Iron-Nickel Alloys for Magnetic Purposes, prepared by J. W. Sands, of The International Nickel Company, Inc., for their "Iron-Nickel Data Book", 1938.*

* *See* Effect of Impurities, *above.*

* For electrical, thermal and mechanical properties of these alloys see "Iron-Nickel Alloys", page 599.

The average effect of nickel on the permeability of iron after annealing, is shown in Fig. 13.[15] No particular advantage is shown over the best grades of iron and iron-silicon alloys although, in the region of 50% Ni, individual alloys were obtained that had unusually good magnetic properties. At still lower magnetizing forces, the optimum composition is 70 to 80% Ni.

Although these are basically iron-nickel alloys, appreciable percentages of other elements are added, in many instances, to develop or accentuate some particular characteristic that is desirable for the application in view.

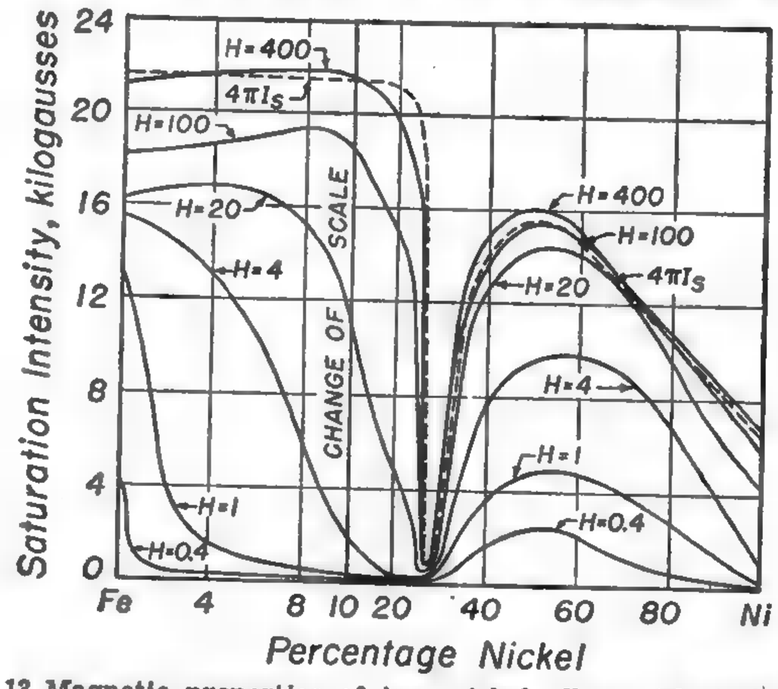

Fig. 13 Magnetic properties of iron-nickel alloys. Electrolytic iron and nickel, melted and annealed in vacuo. From 0.5 to 1.0% Mn added to the alloys containing more than 30% Ni, to facilitate forging.

The trade names, approximate composition and applications of the most important iron-nickel alloys are given in Table II.

Annealed iron-nickel alloys that contain between 30 and 90% Ni, have initial permeabilities higher than that of ingot iron. Alloys that contain more than 50% Ni are sensitive to heat treatment as shown in Fig. 14.[13] The heat treatment that improves initial and maximum permeability, consists in air quenching thin strips on a copper block from the magnetic transformation point. The best results were obtained for alloys containing approximately 80% Ni (the optimum composition is 78½%) and the name "Permalloy" was given to the alloys of this type. Maximum permeabilities of 100,000 are readily obtained with this alloy (Fig. 15) but the saturation value is low (11,000) and the electrical resistivity is only about double that of iron. However, it was found later that the resistivity could be markedly increased by the addition of chromium or

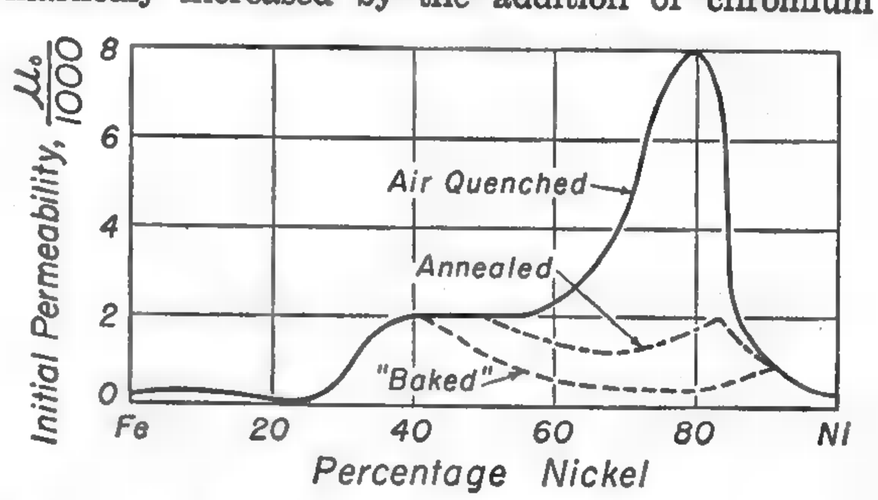

Fig. 14 Initial permeabilities for iron-nickel alloys (Elmen)

molybdenum, while at the same time the necessity for air quenching could be eliminated and the initial permeability could be increased to more than 20,000 (Fig. 15), but at a further sacrifice in saturation value.[14] Table III gives the principal characteristics of the important alloys in this group, and of ingot iron and some other alloys.

50% Ni Iron Alloys. As ordinarily made, the alloys that contain approximately 50% Ni exhibit nothing remarkable (Fig. 13) except that their saturation values are the highest of all iron-nickel alloys above 30% Ni. By ordinary pot annealing, a maximum permeability of 20,000 to

25,000 can be obtained with an initial permeability of 2700, if pure material is used. Such an alloy is 45% Ni listed in Table III. The permeability curve of this alloy is shown in Fig. 15.

The magnetic properties of these alloys can be vastly improved by annealing them in dry hydrogen at 1000 to 1200 C for several hours.[15] This treatment reduces carbon, sulfur and other impurities, but particularly oxygen. In its improved form, the 50% Ni alloy has been given the name "Hipernik" (from high-permeability nickel). Its hysteresis loop is compared with that of silicon iron in Fig. 16. The nickel content, not particularly critical, may be varied from 40 to 60%, but for highest saturation value it should be kept close to 50% (Fig. 13).

Table II. Composition of Commercial Magnetic Iron-Nickel-Base Alloys

Alloy	Percentage nickel
Alloys with Very High Permeability at Low Field Strengths	
Permalloy or Supermalloy	60 to 90 + special heat treatment and sometimes + Cr or Mo
Mumetal	Approx 76 + 6% Cu and 1.5% Cr
Permafy	Approx 80
1040 alloy	72 + 14% Cu and 3% Mo
High-Permeability Alloys for Higher Field Strengths	
Megaperm 6510	65 + 10% Mn
Hipernik	50
Hyperm	50
Nicaloi	49
Audiolloy	48
Permenorm	48
Allegheny Electric Metal	47
Anhyster C and D	45 to 50
Radiometal	45 to 50
2129	45 to 50
Megaperm 4510	45 + 10% Mn
Moderately High-Permeability Alloys of High Electrical Resistance	
Rhometal	40 to 45 + 5% Cr and 3% Si
Gamma	Approx 35
Anhyster A and B	Approx 35
Alloys with Constant Permeability over a Range of Flux Densities	
Perminvar	20 to 75 + 5 to 40% Co + special heat treatment and sometimes + Mo
Conpernik	50 + special heat treatment
Isoperm	40 to 55 + special treatment
Isoperm (precipitation types)	36 to 50 + 9 to 15% Cu 40 to 60 + 3 to 4% Al
Alloys with Permeability Varying with Temperature	
Compensator alloy	29 to 32.5
N30	30
Thermoperm	30
N. M. H. G.	30

The use of this alloy instead of ordinary 4% Si iron for transformer cores, would result in a reduction of energy losses to about one-half. However, because of the high cost, the use of this alloy is limited to special transformers, such as current transformers in which, because of high permeability and low loss, the ratio errors and phase-angle deviations are almost entirely eliminated. Cold rolled in the form of continuous ribbon, this alloy is particularly suitable for the bushing type of current transformers, since in this way there is no waste of material.

Although this 50% Ni alloy cannot compete with the higher-nickel alloys for applications that require the highest initial permeability, it is preferable for most other uses, because of its higher saturation value (Fig. 13).

In Table IV are listed the magnetic properties of this alloy in comparison with values for other alloys.

Miscellaneous. Numerous modifications have been made in these alloys by the addition of other elements and by variation in the heat treatment. The most important of these modifications are listed in Table V.

Some of these alloys have been improved greatly by cooling in a magnetic field through the magnetic transformation point.[16] Particularly good results were obtained with 65% Ni iron and with 45% Ni – 30% Fe – 25% Co. A maximum permeability of more than 600,000 was reported for the 65% Ni alloy. Still higher values have been reported for a 79% Ni – 5% Mo alloy—called "Supermalloy"—annealed in dry hydrogen at 1300 C[16] (*see* Table III).

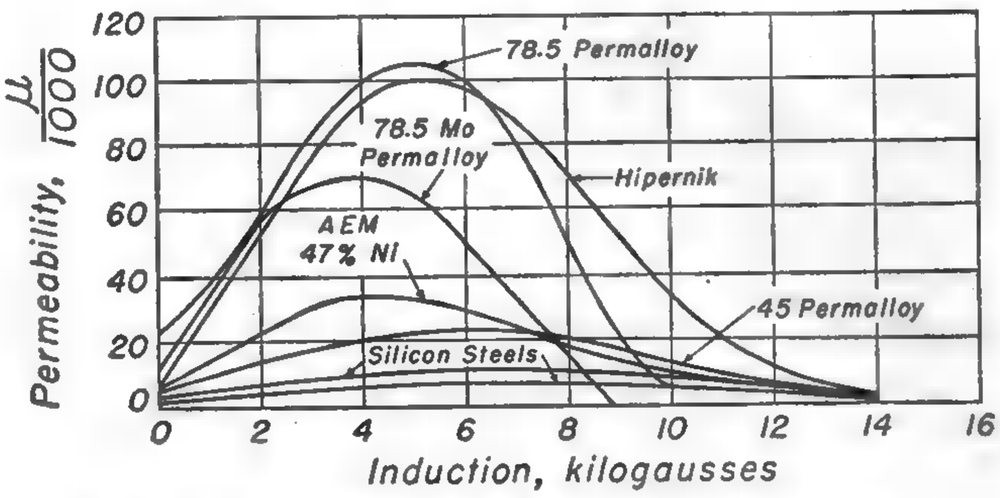

Fig. 15 Permeability curves for various magnetic alloys (Wise)

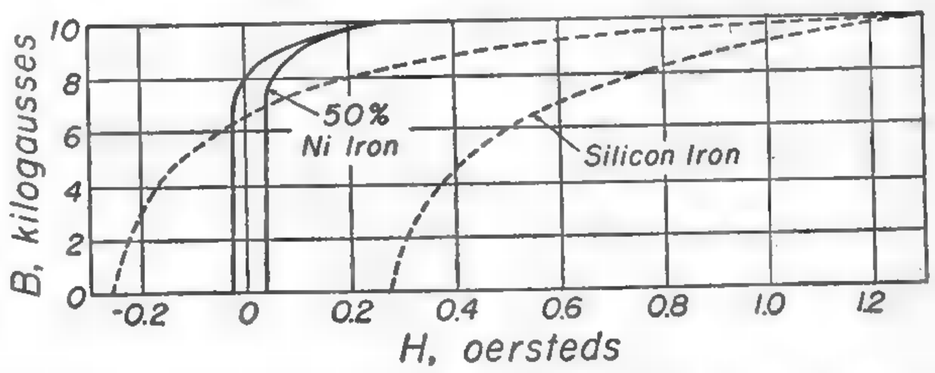

Fig. 16 Comparative hysteresis loops of Hipernik and silicon iron

Materials with High Magnetic Saturation Value. Iron has a saturation value of 21,600 ($4\pi I_s$). To exceed this value, it is necessary to alloy iron with cobalt in amounts between 0 and 65%. The highest value is obtained by using 34.5% Co[17] (Fig. 5); the value for this composition is approximately 24,200.[18] Alloys in the range from 25 to 50% Co would find wide applications in industry were it not for the following disadvantages.

1 The price of cobalt for metallurgical uses is $1.50 per lb, so the raw materials needed to make the 35% alloy, cost about 60 cents per lb; the 50% alloy 80 cents per lb.
2 As ordinarily made, the alloys above 30% Co are very brittle, much like high-silicon iron.
3 Aside from the high saturation value, the magnetic properties after ordinary heat treatment are poor (low permeability and high hysteresis loss).
4 The electrical resistivity is low (Fig. 4).

Table III. Magnetic Properties of Various Alloys

Material[a]	Initial Permeability	Maximum Permeability	Hysteresis Loss, ergs per cu cm per cycle[b]	Residual Induction, gausses	Coercive Force, oersteds	Saturation Value, gausses[c]	Resistivity, microhm-cm
Ingot iron	250	7,000	5000	13,000	1.0	21,600	11
4% Si iron	600	6,000	3500	12,000	0.5	20,000	50
78.5 Permalloy, quenched	10,000	105,000	200	6,000	0.05	10,700	16
45 Permalloy	2,700	23,000	1200	8,000	0.3	16,000	45
3.8–78.5 Cr-Permalloy	12,000	62,000	200	4,500	0.05	8,000	65
3.8–78.5 Mo-Permalloy	20,000	75,000	200	5,000	0.05	8,500	55
5-79 Mo-Supermalloy	100,000	800,000	20[d]	6,000[d]	0.004	8,000	60
45-25 Perminvar, baked	400	2,000	2500	3,000	1.2	15,500	19
7-45-25 Mo-Perminvar, baked	550	3,700	2600	4,300	0.65	10,300	80
70-7.5 Perminvar, annealed	750	3,500	....	....	0.8	12,000	16

(a) Single numbers preceding the word "Permalloy" indicate the nickel content, and double numbers signify first the content of chromium or molybdenum, and second, the nickel content; the remainder is iron in each alloy. The two high numbers before "Perminvar" indicate the nickel and cobalt contents, respectively, and the small initial number indicates the molybdenum content. These alloys have constant permeability up to a certain value of H.
(b) For saturation value of the flux density. (c) Saturation value of the intrinsic induction. (d) Approximate value.

However, when small amounts of certain elements are added, such as vanadium and chromium, and special treatments are included among the processing operations, the 35% Co alloy can be cold rolled commercially to any gage, and the cold rolled strip is sufficiently ductile to be punched and sheared for any purpose. Furthermore, annealing processes have been developed for producing magnetic properties suitable both for d-c and a-c applications. Alternating-current applications necessarily require low eddy-current losses and low hysteresis. Eddy-current losses can be kept low by a combination of the alloying elements mentioned above and a judicious selection of gage. The 35% Co alloy has been named "Hiperco".

Figures 17 and 18 show typical *B-H* curves, and loss curves for Hiperco in comparison with other commercial materials; the 1% Si iron is commonly used for applications that require high saturation values. Figure 18 shows that lower losses apparently can be obtained with a high-silicon iron (4 to 5% Si) rolled to 0.010 in. than with 0.010-in. Hiperco; however, it is impossible to use the high-silicon iron at flux densities above 19,000 gausses. The exciting current would be prohibitive.

The only material that can be used for comparison is the 1% Si iron. When this iron has been rolled to 0.010

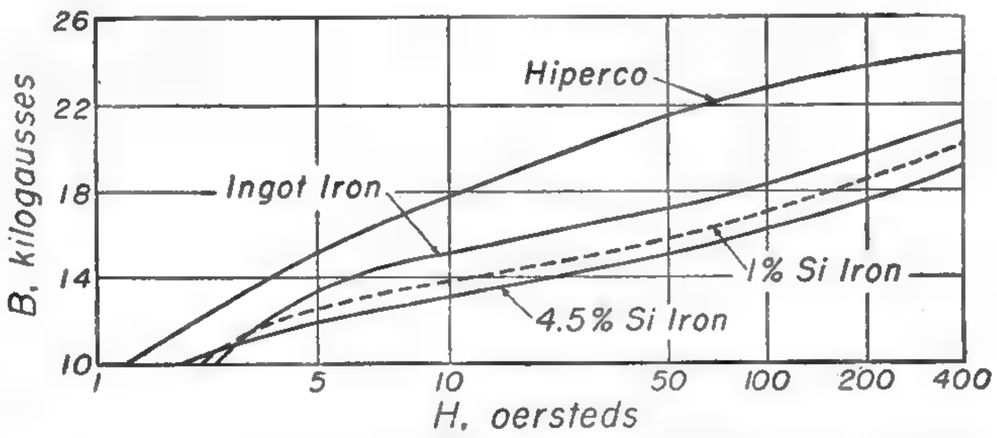

Fig. 17 Comparative *B-H* curves for Hiperco and other materials of high saturation

in. its losses at 20,000 gausses, though comparable with the losses for Hiperco at 60 cycles, are much higher than those for Hiperco at 600 cycles (about double). Even if, from a loss standpoint, 1% Si iron could be used at 20,000 gausses, the magnetizing current would be more than 13 times as high as that for Hiperco. For the same value of H (for example, 30 oersteds) Hiperco can be operated at 20,000 gausses, while 1% Si iron will reach only 15,500, a ratio of 1.3 to 1.0. The chief advantage in using Hiperco is, therefore, that considerably less material is required.

The cost of Hiperco is perhaps ten times that of 1% Si iron rolled to the same gage. For most applications this cost would be prohibitive, but in special uses where saving in weight or space is important, or where it is imperative to obtain the highest possible flux density irrespective of cost per pound, Hiperco or Permendur should be considered. (*See below.*)

According to Elmen,[18] a 50% Co alloy with the addition of 1 to 2% V, can also be forged and cold rolled after

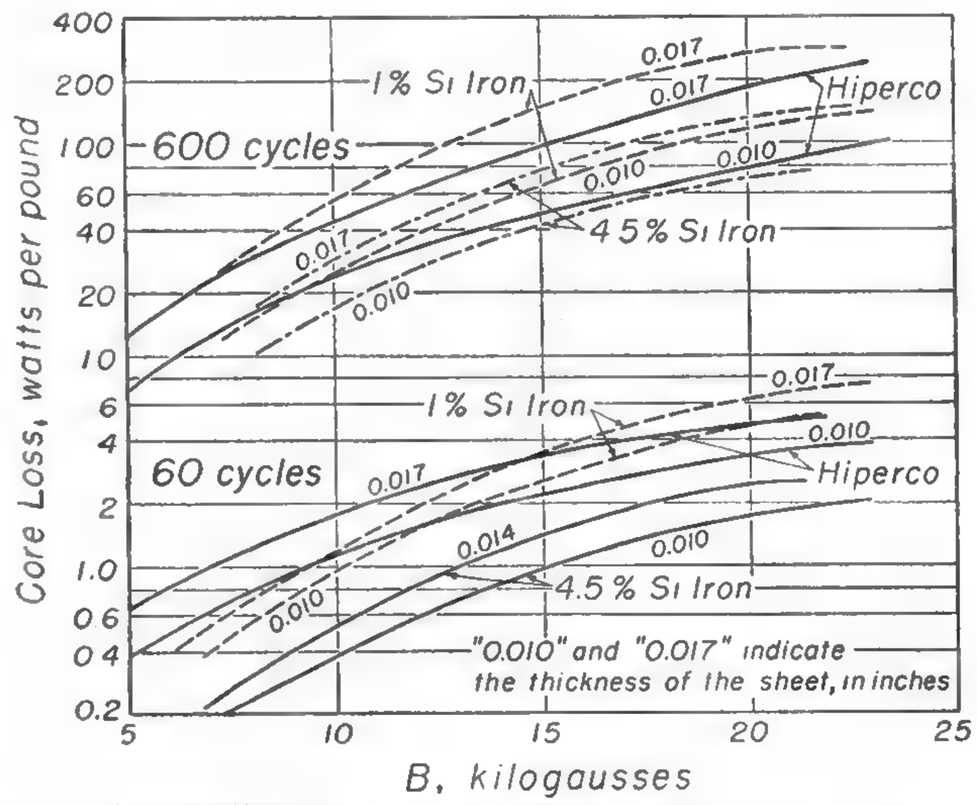

Fig. 18 Comparative curves of watt losses versus induction for Hiperco and other materials of high saturation

special treatments[19] and, because of its slightly better magnetic properties in the range between $H = 10$ and $H = 100$ (*see* Fig. 25), is preferable to the 34.5% alloy for certain applications where cost is of no importance. The name "Permendur" has been applied to this alloy.

Materials with Constant Permeability. *Compressed Metal Powders.* The permeability of ferromagnetic materials is inherently not constant (Fig. 6 and 7). For many purposes, as for filter coils in radio and telephone circuits and for loading-coils for long-distance telephone transmission lines, it is essential that the permeability be constant in order to give fidelity to the reproduction of sound. A concentrated air gap in the core was used at first, but was soon discarded because of the effect of the leakage

flux on the surrounding circuits. Distributed air gaps, such as are obtained by means of compressed insulated iron powder, were resorted to with good results for audio frequencies.[20] Using annealed and uninsulated 80-mesh electrolytic iron powder, compressed into ring cores at 100 tons per sq in., Bell laboratories in 1921 reported cores with a constant permeability of about 75 up to $B = 100$ gausses.

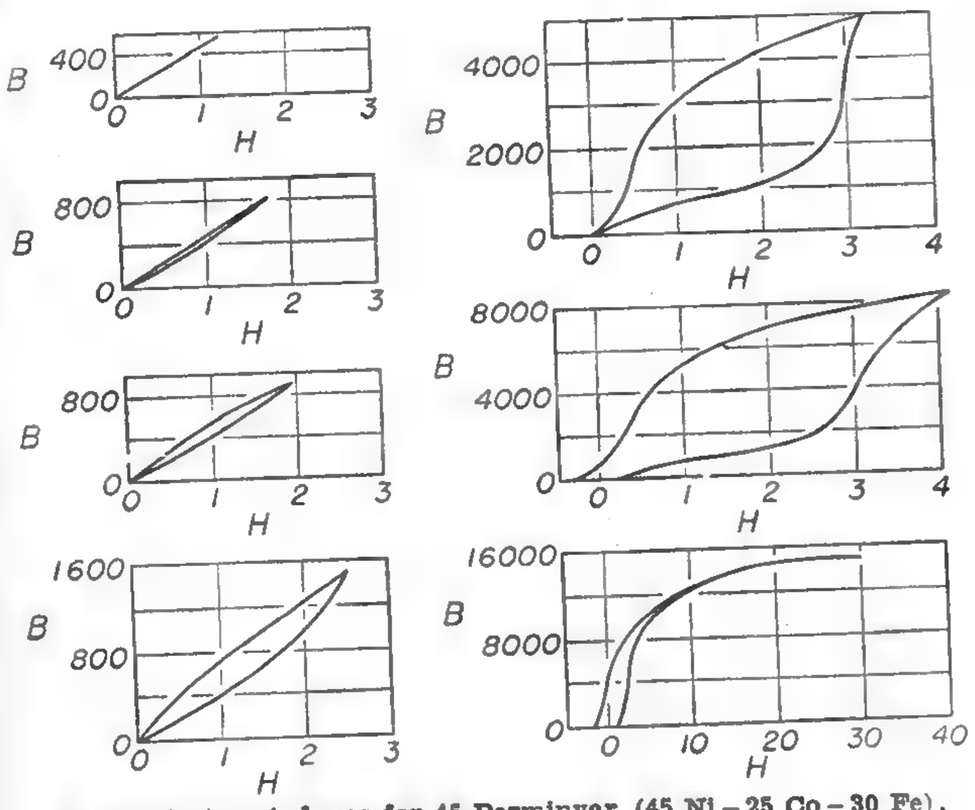

Fig. 19 Hysteresis loops for 45 Perminvar (45 Ni – 25 Co – 30 Fe), annealed

For the same material, when unannealed iron was used, the permeability was about 50.

When the iron powder was insulated with shellac, the permeabilities decreased to 55 and 25 respectively; the permeability was nearly constant up to $B = 100$. Although the permeability is lower than for the uninsulated powder, the eddy-current losses are much lower (about one-tenth), thereby greatly increasing the X_L/R values, a factor of vital importance for loading-coils and filter-coils.

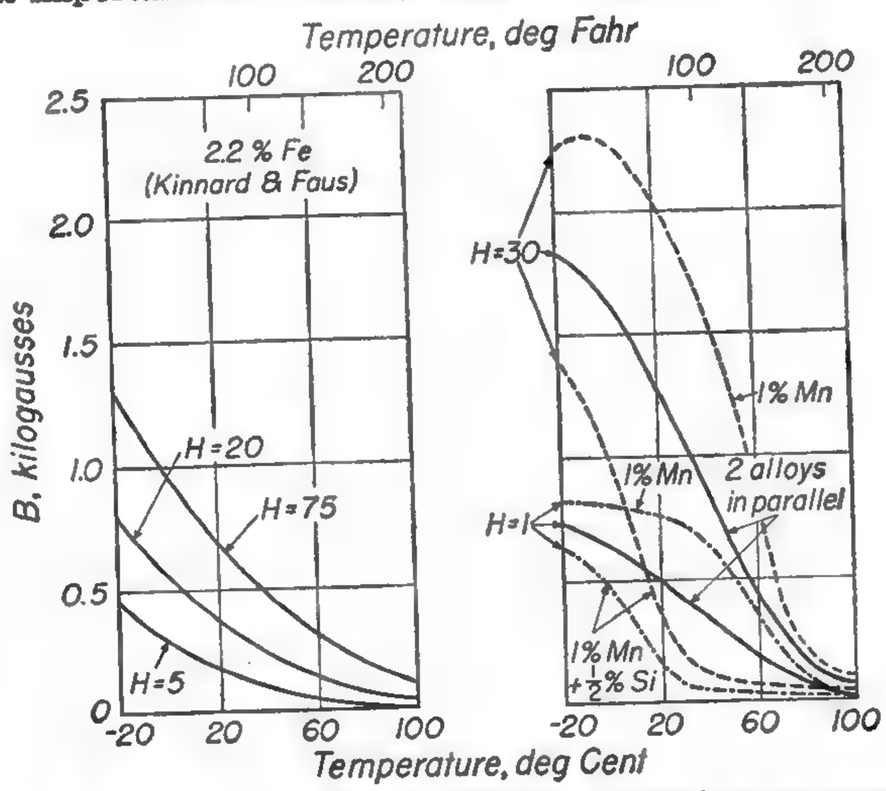

Fig. 20 70 Ni – 30 Cu type of magnetic temperature-compensator with modifications in composition as shown. (*Left*) Calmalloy. (*Right*) Westinghouse alloy

During the late 1920's, hydrogen-reduced iron[21] and carbonyl iron were introduced. Their greater fineness (1 to 40 microns) and uniformity of size and shape, made them particularly suitable for use at radio frequencies.[22]

Rolled Strip. Higher permeabilities than with compressed powders, can be obtained with certain alloys rolled into thin strip and heat treated to give constant permeability over a given range of B.

Certain Fe-Ni-Co alloys[24] called "Perminvars" have been developed, containing about 30% Fe, 45% Ni and 25% Co. Figure 19 shows the hysteresis loops for the optimum composition, having a constant permeability of about 400, up to $B = 1000$, and consequently very nearly zero hysteresis. Similar, but inferior, results can be obtained with 50% Ni iron by means of a special heat treatment, which is an incomplete anneal below 800 C (Conpernik[25]). Permeabilities from 1000 to 2000 are obtainable, constant to $B = 200$ within $\pm 5\%$. (For B-H curve see Fig. 25.)

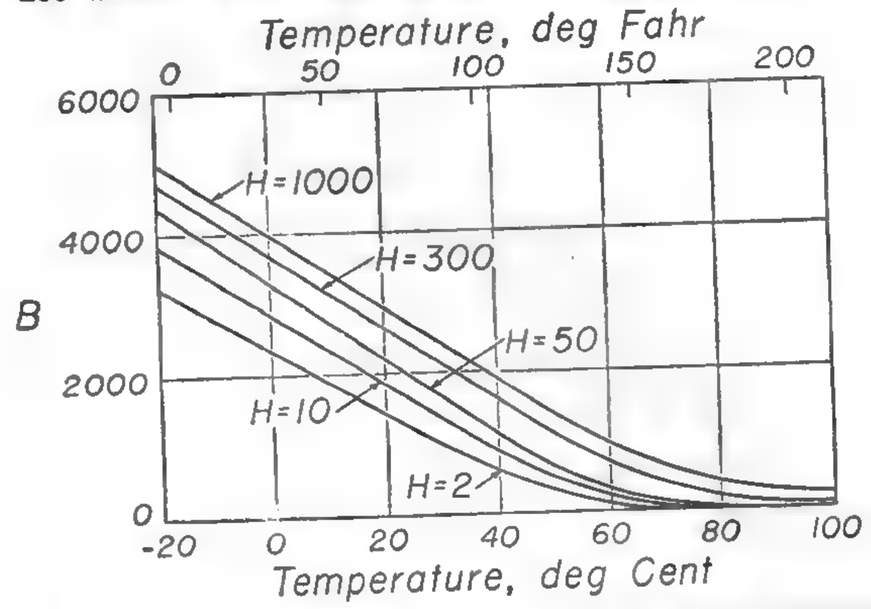

Fig. 21 Data for the 30% Ni type of magnetic temperature compensator, Thermoperm (Stäblein)

A more recent development[26] in Germany has resulted in iron-nickel alloys called "Isoperms", containing 35 to 55% Ni, 45 to 50% Fe and 5 to 15% Cu. The alloy is first drastically cold rolled, then quenched from a high temperature, further cold rolled, and finally annealed—a treatment by which the copper is precipitated in such a way as to produce a preferred crystallographic arrangement that results in low retentivity and constancy of permeability (50 to 60) over a wide range of H (0 to 100 oersteds) (*see* Fig. 25).

Another method[27] for accomplishing similar results consists in welding together thin plates of different compositions, having different coefficients of expansion, and magnetostriction of opposite sign. Thus 90 to 100% Ni iron, which has negative magnetostriction, or stainless

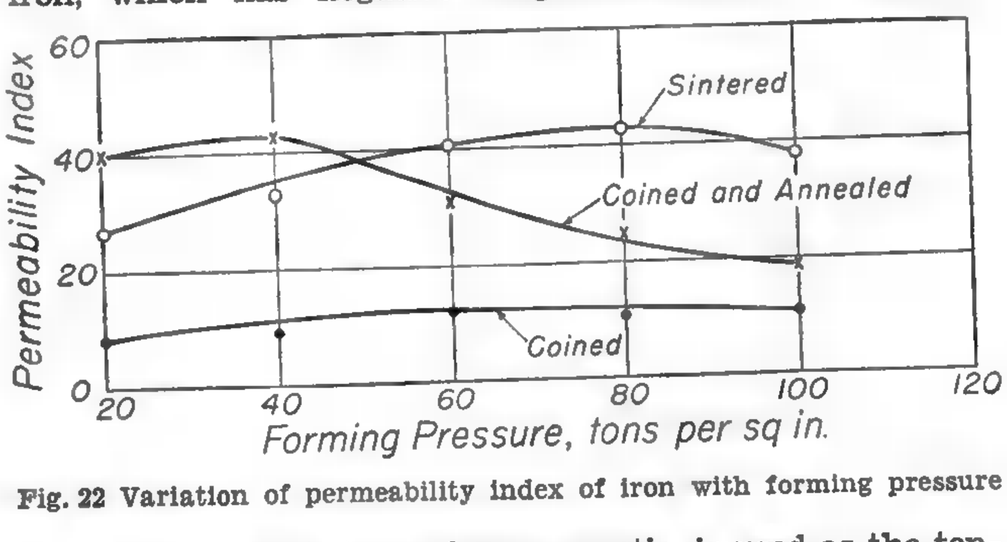

Fig. 22 Variation of permeability index of iron with forming pressure

steel (18-8), which is nonferromagnetic, is used as the tension component, while 36 to 50% Ni iron, which has positive magnetostriction, is used as the compression component. After the proper amount of cold rolling and annealing, a laminated structure is produced which, because of the uniform strains throughout, results in a constant permeability (60 to 120) over a wide range of H (0 to 150 oersteds).

Alloys for Magnetic Temperature Compensation. Because the magnetic permeability of iron and iron alloys decreases with temperature (except for low values of H) the reading of electrical meters that depend on the flux produced by a constant voltage supply or by a certain load current (for example, watt-hour meters) decreases with the ambient temperature. To compensate for such errors it is customary to shunt a certain amount of the magnetic flux around the moving part of the meter by means of an alloy that has an unusually high magnetic temperature coefficient, between 0 and 100 C, so that as the ambient temperature increases, the amount of the shunted flux decreases, forcing more of the flux through the moving member than would be possible otherwise.

Vane-type instruments	>50,000 for $B = 5{,}000$	16,000	<150	....	...	45	Hipernik*

* Or equivalent

(a) "W 10/60" means "watt loss for B = 10,000, frequency = 60 cycles". "W 15/60" means "watt loss for B = 15,000, frequency = 60 cycles".

(b) For W 10/400 the total watt loss is less than 1.9 per lb

(c) For W 10/400 the total watt loss is less than 1.5 per lb

(d) For aircraft apparatus, watt losses per pound are as follows: W 20/60, <4.20; W 10/600, <22; W 15/600, <50; W 20/600, <80.

By correct proportioning of the parts, it is thus possible to compensate almost entirely for the temperature changes. Alloys for such purposes are essentially of two types:

1 The nickel-copper type that contains about 70% Ni, 30% Cu as well as certain admixtures, such as 2% Fe ("Calmalloy"[28]), or about 1% Mn with or without a small amount of silicon (Westinghouse Alloy). Characteristic curves are shown for these alloys in Fig. 20.

2 The nickel-iron type containing 30 to 40% Ni with a small amount of manganese, chromium and silicon. Curves for this type of alloy ("Thermoperm") are shown in Fig. 21.[29] The curves are nearly straight lines all the way from low temperatures up to 60 C, and the temperature coefficients are higher than for the monel type of alloy.

Sintered Compressed Iron Powder.* For many applications in which the magnetic circuit is complicated and would require considerable machining, it is often advantageous to make the parts by pressing iron powder into a mold and sintering the parts thus made, in a reducing atmosphere. In Fig. 22, 23 and 24 are shown the effects of forming pressure, sintering temperature and sintering time, on the magnetic permeability of iron for a constant magnetizing force, as a percentage of the permeability of annealed hot rolled low-carbon steel.

From these curves it appears that a pressure of 80 tons per sq in., combined with a sintering temperature of 1200 C for 3 hr, yields magnetic properties equal to or better than those of annealed hot rolled low-carbon steel or wrought iron.

Summary. As a summary, Fig. 25 shows *B-H* curves for materials considered in this article, and Table VI shows applications in electrical apparatus and instruments, with the required or desired magnetic and electrical properties and the corresponding alloy that will serve best.

Permanent Magnet Materials

By K. L. Scott*

TWO TYPES of permanent magnet material are in wide use today; namely, the magnet steels, which contain carbon as a hardening constituent, and the more recently developed magnet alloys, which are virtually free from carbon. A third type, composed of metallic oxides, has a limited field of use. Particularly great progress has been made since about 1925 in the development and improvement of the carbon-free type of material. In the present article the first type will be referred to as magnet *steels* and the second type as magnet *alloys;* the oxide magnets will receive little discussion.

Theoretical Discussion. In order to understand the relative importance and usefulness of each type of material, a brief summary of the fundamental theory of permanent magnets will be given. In Fig. 1 are shown a typical hysteresis loop and magnetization curve for a permanent magnet alloy. The variables are magnetizing force H, in oersteds [0.1 (4π) times the ampere turns per centimeter] as abscissas, and magnetic flux density or induction B, in gausses (so-called "lines of force" per square centimeter) as ordinates. Starting with an unmagnetized specimen, if increasing values of H are applied (as by gradually increasing the electric current in a coil or wire wound on the specimen) the corresponding values of magnetic flux produced in the specimen will be as shown by the familiar S-shaped magnetization curve, also called the "normal induction curve". If the values of H are gradually decreased from the highest applied value, H_{max}, to zero, and then increased in the negative direction to a negative H_{max} (accomplished by reversing the current in the magnetizing winding), the value of B will change from a positive B_{max} to a negative B_{max} along the left-hand curve of the hysteresis loop. If this process is repeated, starting with a negative H_{max}, the right-hand side of the hysteresis loop will be traced. If the value of magnetizing force is reduced from H_{max} to zero (as by opening the circuit of the magnetizing winding) the value of B will drop from B_{max} to the intersection of the hysteresis loop with the B axis. The value of B at the point of intersection is called the "residual induction", designated B_r. If sufficient negative magnetizing force is applied now to reduce the value of B from B_r exactly to zero, the value of negative H required will be as shown by the intersection of the hysteresis loop with the H axis. This particular value of H is called the "coercive force", designated H_c. This quantity affords a measure of the resistance of a material to demagnetization.

It is appropriate to distinguish here between the total induction B and the intrinsic induction B_i, which is that part of the total induction B caused by the presence of the magnetic material. B_i is equal to $B - H$, and is numerically equal to B only when $H = 0$, as shown in Fig. 2, in which hysteresis loops based on B and B_i are shown for the same cycle of magnetization. It is to be noted that the values of B_r are the same for both loops, but the value of coercive force for the B_i loop, designated H_{ci}, is greater than the value of H_c. The difference is significant for the magnet alloys that have high values of coercive force, since in some instances H_{ci} affords a more accurate measure of the permanence of a magnet (that is, its resistance to demagnetization) than H_c.

The descending branch of the hysteresis loop between the points B_r and H_c is most important in the theory of permanent magnets. It is known as the "demagnetization curve". If the product of the coordinates B and H of this curve are plotted against corresponding values of B, a new curve is obtained, as shown in Fig. 3. The maximum value of the product $B \times H$—designated $(BH)_{max}$—as obtained

* Western Electric Company, Chicago

from this curve, is proportional to the maximum amount of magnetic energy that a magnet of the given material can support in an air gap, per unit volume of material in the magnet. Hence, the most efficient design for a magnet will be one that works the magnet at the flux density corresponding to the $(BH)_{max}$ point of the material.

Since the value of $(BH)_{max}$ is proportional to the maximum obtainable air-gap energy per unit volume of a magnet, $(BH)_{max}$ constitutes the best criterion of the magnetic quality of a permanent magnet material. The co-ordinates of the $(BH)_{max}$ point can be located to a close approximation by the intersection of the diagonal of the rectangle that has sides OB_r and OH_c, with the demagnetization curve, as shown in Fig. 3. The $(BH)_{max}$ point can also be located quite well by the point of tangency on the demagnetization curve, of a straight line parallel to a line through B_r and H_c. However, this method will

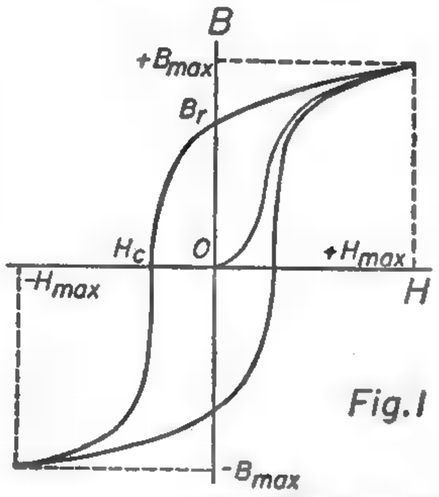

Fig. 1

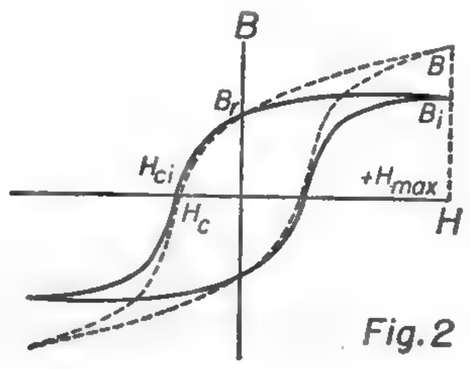

Fig. 2

Fig. 1 Typical hysteresis loop of permanent magnet alloy
Fig. 2 Hysteresis loops showing relation of intrinsic or ferric induction B_i and total induction B

not work for materials with characteristics such as are illustrated in Fig. 8. For the magnet *steels* and some of the magnet *alloys*, the product $B_r \times H_c$ is directly proportional to $(BH)_{max}$ and hence gives an approximate indication of magnet quality. The co-ordinates B and H of the $(BH)_{max}$ point are equal respectively to approximately $0.65B_r$ and $0.65H_c$. Hence the values of B_r and H_c for these materials, are useful as inspection criteria and also indicate approximately the proper working flux density for purposes of design.

It has been shown also that the flux density of a fully magnetized bar magnet, designated B_{rem}, depends on the length L and equivalent diameter D in the manner shown in Fig. 4. This curve holds for most permanent magnet materials, but applies strictly only to straight bars. However, the curve will also apply quite well to magnets of other shapes, unless the ends of the magnets are relatively close together, or are brought effectively close together by iron pole pieces. The preceding simplifications are not permissible for magnet *alloys* such as Alnico 5, for which the demagnetization curve is more concave towards the origin. Thus the product of $B_r \times H_c$ is not a good criterion of quality for Alnico 5. In general, magnet design should be based on actual demagnetization curves and actual values of the energy product.

Testing of Magnet Materials and Magnets. Most manufacturers and large users of permanent magnet steels or alloys, test the materials for magnetic quality by measuring B_r and H_c, and $(BH)_{max}$. After suitable heat treatment, straight bars of cast or rolled material are tested in some form of permeameter. For methods and equipment for making these tests, see ASTM Method A34-46.

Most users of magnets also make a flux test on the finished magnets. This test can be made most accurately with a search coil and a flux meter of the galvanometer type. Greater speed and sufficient accuracy for commercial purposes can be obtained in many instances by using a flux meter of the d-c meter type, in which the test magnet furnishes the field to deflect the moving coil of the meter; or by adapting an a-c meter of the iron vane type. Some have used voltage measurements from air-core coils rotating in the field or air gaps of strong magnets.

Aging of Magnet Materials and Magnets. The magnetic properties of the permanent magnet *steels* are not stable with time; the residual induction and coercive force of most of them begin to change spontaneously as soon as the steels are hardened, and continue to change for an indefinite time. The rate of change is greatest immediately after hardening, and decreases rapidly so that in a few days the rate is low. The rate and amount of change differ for different kinds of steel and are not uniform for any given kind of steel. The direction of the change is always for the residual induction to increase and the coercive force to decrease. Because of this instability it is good practice for a user of magnet *steel,* buying under specifications of magnetic properties, to allow an aging period between the hardening and testing of test bars.

Because of the nature of magnet *alloys* and the kind of heat treatment employed for them, such aging phenomena are much less pronounced in the magnet *alloys* and are negligible for most purposes.

The state of magnetization of magnetized steel magnets is also subject to a peculiar instability. It is observed that magnets magnetized immediately or soon after hardening, but not subjected to adverse fields, will suffer a spontaneous decrease in flux, beginning immediately after magnetizing. The rate of loss of flux is greatest immediately after magnetization, and decreases rapidly with time, so that after several days the flux has reached an approximately stable value. If the magnet is remagnetized, the same phenomenon is repeated, but less flux is lost than the first time. The phenomenon, however, is only temporary, and disappears when sufficient time has elapsed after hardening, so that if a magnet is magnetized after standing at room temperature for about four weeks after hardening, the subsequent spontaneous loss in flux will be negligible. This phenomenon appears to be present in the magnet *alloys* only to a negligible extent, if at all.

The loss of flux that occurs in magnets because of external demagnetizing influences is also commonly but improperly referred to as "aging". External demagnetizing influences include mechanical shock, heat, and adverse magnetic fields, including a-c fields and the fields of other

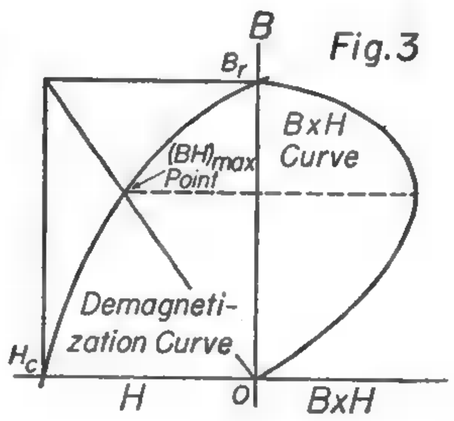

Fig. 3

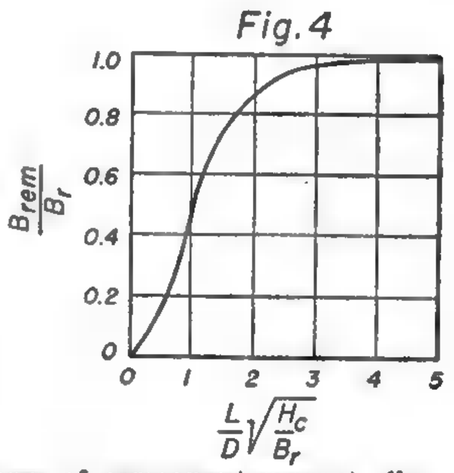

Fig. 4

Fig. 3 Typical demagnetization curve of permanent magnet alloy
Fig. 4 Relation between magnetic properties and dimensions of straight bar magnets

magnets. In general, if a magnet is weakened by any one of the above means and not remagnetized, it will not be further weakened by a repetition of the same treatment, and will suffer only a slight loss in flux from the application of any other treatment that would have weakened it originally by about the same amount. In the process inspection of magnets after hardening, some users follow the magnetizing operation by a partial demagnetization or aging before testing, for the purpose of eliminating magnets that are improperly heat treated or made of defective material. If a stabilizing treatment is required, as for magnets to be used in measuring instruments, the material may be stored for a long time, subjected to heat (as by immersion in boiling water) or partially demagnetized by an a-c or d-c field after final magnetization.

Methods of Magnetizing Magnets. The problem of magnetizing permanent magnets has become increasingly difficult with the advent of materials that have coercive forces in the range of 500 oersteds and higher. The magnetizing field required for magnetizing a magnet fully is from four to five times the coercive force of the material, ranging from 250 amp-turns per cm for the chromium and tungsten steels to 2500 amp-turns per cm for some of

Table I. Commercial Types of Magnet Steels

Type of Steel	Nominal Composition,[a] percentage						Nominal Magnetic Properties[b]		Hardening Temperature, deg Fahr	Quenching Medium
	C	Mn	Cr	W	Co	Mo	B_r, gausses	H_c, oersteds

Co-Cr	0.95	0.30	9.00	...	16.00	1.30	8,000	180	(c)	Air
Co-W	0.85	0.50	2.00 to 5.00	8.75	17.00	...	9,000	165	1750	Oil

(a) Limits usually 0.30% Si max, 0.03% P and S max, 0.50% Ni max
(b) Values for previously annealed materials usually 5 to 10% lower in H_c
(c) Heat treatment: 2100 F, cool in air; 1850 F, cool in air.

the magnet *alloys*, such as Alnico 4. Most magnets made of steels and alloys that have low coercive force, can be fully magnetized by means of large electromagnets. Some magnets that have high coercive force and favorable shapes, can also be magnetized by the same means; but magnets of more intricate shapes or greater length may require the use of a magnetizing winding of very heavy wire carrying large currents. Water-cooled copper tubing carrying hundreds or thousands of amperes has been used for some applications. Banks of heavy-duty rectifiers or low-voltage high-current d-c generators, such as plating generators, are suitable sources of current. Short-duration heavy current pulses from half-cycle welders, or large banks of condensers have also been employed successfully. The advantage of these methods over the use of electromagnets is that the required high field strengths can be obtained readily and at the same time the direction of the field can be made to conform to the desired path of flux through the magnet, by suitable shaping of the winding. Where the current flow is of short duration, a lighter and more easily manipulated winding may be used.

Magnet Steels. The types of magnet *steel* produced commercially in the United States are classified by their manufacturers as follows: carbon-manganese, chromium, chromium-molybdenum, tungsten, chromium-tungsten, and various grades of cobalt steel, including cobalt-chromium and cobalt-tungsten. The chromium steels are made in grades ranging from nominal 1 to 6% Cr; the tungsten steels range from 5 to 6% W; and the cobalt steels contain from 3 to 36% Co, with chromium from 2 to 10%, and a fraction of 1% Mo in certain steels. Some tungsten steels contain enough chromium to make them oil-hardening. Otherwise the tungsten steels, the 2% Cr steel and the carbon-manganese steels are water-hardening, and all the rest are oil-hardening. It is noteworthy that the 1% Cr steel has the best magnetic properties when quenched in oil; but water, some water solution, or a light oil is recommended for the 2% Cr steel. Data concerning the various types of magnet *steel* are shown in Table I. Only those types reported by various American manufacturers are included, and the data serve to summarize information furnished by the manufacturers.

Manufacture of Magnet Steel. In general, the methods of melting, rolling and fabricating magnet *steels* are similar to those used for tool steels of similar composition. Exceptions arise from the fact that mechanical properties are of secondary importance and practices that would be harmful to the magnetic properties must be avoided as much as possible. This means that the thermal history of the steel should be as brief as can be. Rolling or forging should be accomplished with a minimum amount of reheating, and overheating should be avoided. The steel should not be annealed unless necessary for machining operations, and the anneal should be as light as is consistent with machinability.

If the magnetic properties are impaired by overannealing or overheating, it is possible to restore a good measure of the loss by a normalizing treatment, quickly heating and cooling the material from a temperature well above the transformation range. Normalizing temperatures in use range from 1700 to 2300 F for 5% W steel, and from 1700 to 2000 F for chromium steel.

Melting and Rolling. Magnet *steels* are almost always melted in electric furnaces, either arc or induction.

Hot Forming. In many instances, the shapes of permanent magnets are such as to require hot forming. This may be done satisfactorily at temperatures between 1400 and 1800 F. Higher temperatures are detrimental to the quality of the steel. A medium temperature is preferable and the heating and forming should be done as quickly as possible. Magnets are usually air-cooled after forming. Sometimes magnets are hardened by quenching immediately after the forming operation; thus one heating operation may be eliminated. This practice requires better than ordinary control of the forming temperature.

Annealing. Great emphasis should be placed on the desirability of designing magnets so that they do not require annealing for machining operations. When the need is unavoidable, or when cold forming or blanking is the chosen fabricating process, as light an anneal as possible should be used, because annealing always impairs the magnetic properties of a magnet *steel.* However, grades of steel that are air-hardening must be annealed by the fabricator after the hot forming operation if the formed magnets are to be machined. If hot forming is not required or if the machining can be done before forming, the material can be annealed at the mill. Magnet *steel* should be heated to the annealing temperature quickly, held at temperature only long enough to be heated through, and cooled just slowly enough to avoid air-hardening. Cooling from 1000 F to room temperature may always be done in the open air.

Hardening. The recommended hardening temperatures are listed in Table I. The optimum hardening temperature is usually the one that gives the highest value of $(BH)_{max}$, or of the product $B_r \times H_c$. However some magnets are not proportioned for maximum efficiency and require higher values of B_r or H_c than are associated with the maximum value of $(BH)_{max}$ or the product $B_r \times H_c$, because high values of B_r are best for long or slender magnets and high values of H_c for short thick magnets. Oil-quenching results in higher values of H_c and lower values of B_r than water-quenching. A much greater amount of warping, cracking and breaking results from water-quenching. For this reason oil-hardening steels are gradually replacing water-hardening steels for most applications. Magnets should not be held at the hardening temperature longer than is necessary for the solution of carbides. A prolonged soak at the quenching temperature is usually detrimental to the magnetic properties of magnet *steels.*

Grinding. Hardened magnets should be ground very carefully in order to avoid grinding cracks, which sometimes develop hours after the grinding operation. Wet grinding, light cuts, and careful selection of the abrasive wheel are the best safeguards against grinding cracks. In general, a grinding practice that is suitable for tool steel will be suitable for magnet steel.

Magnet Steel Castings. Cobalt steel magnets of more or less intricate shapes have frequently been produced by casting. The properties of cast cobalt steel do not differ greatly from those of forged or rolled steel, although the

(a) B_i and H_{ci} values are on the basis of intrinsic induction.
Data from the General Electric Company, including demagnetization curves

coercive force is usually higher and the residual induction lower. The same annealing and hardening practices are recommended. The cast material is ordinarily more brittle than the forged. Casting the other magnet *steels* affords no appreciable advantage.

Miscellaneous. The magnetic properties of magnet *steels* have not been correlated reliably with the microstructure. In general, a fine, silky fracture is associated with good material. Of course decarburization should be avoided. After hardening, heating above 212 F is detrimental to the magnetic properties. Serious impairment begins to take place between 300 and 400 F. Defective magnets may frequently be reclaimed by rehardening. For immersing magnets during water-quenching, there is no standard method that will minimize warpage or breakage. In handling magnets that must be formed to size just before the

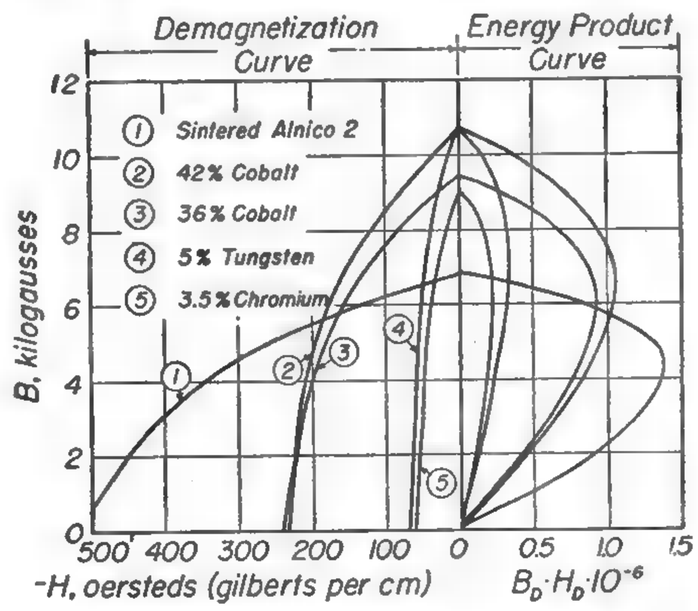

Fig. 5 Demagnetization curves and energy product curves of various magnet materials

quench, the tongs should make as little contact as possible with the magnets to avoid cooling them too much by contact with cold metal before the quench.

Magnet Alloys. The range of possibilities for the design of permanent magnets has been extended greatly by the introduction of alloys that are substantially free from carbon. The magnetic properties of any of the permanent magnet *steels* can be substantially duplicated by some of these alloys. Furthermore, materials are commercially available that have far greater coercive force and residual induction values than any of the magnet *steels*, and other such alloys are being developed. The following materials of this class are known or are in use at the present time

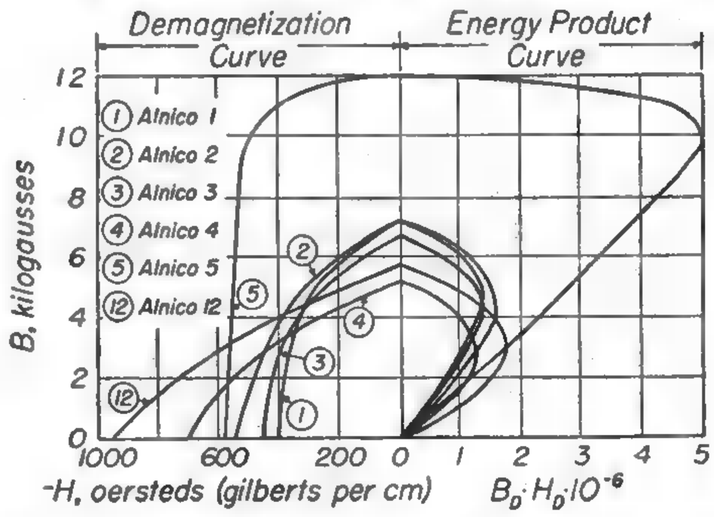

Fig. 6 Demagnetization curves and energy product curves of various magnet alloys

(but not all are commercially available): an alloy of iron, cobalt and molybdenum, known as Remalloy or Comol; various alloys of iron, nickel, aluminum and one or more other elements—cobalt, copper and titanium—with the common name of Alnico, plus an Arabic or Roman numeral to designate the grade; a series of alloys of copper and nickel with iron or cobalt or both, bearing the derived names of Cunife or Cunico; an alloy of silver, manganese and aluminum known as Silmanal; an alloy of platinum and cobalt that has extremely high coercive force; an alloy of cobalt, iron and vanadium called Vicalloy; and a mixture of iron and cobalt oxides called Vectolite (Table II).

Remalloy or Comol has magnetic properties slightly better than 36% Co steel. Magnets are produced from hot rolled or hot forged bars, or may be cast. The metal may be hot formed at or near 2000 F. The range of hot forming temperatures is rather narrow. After a solution heat treatment between 2200 and 2400 F, followed by an oil quench, the alloy is readily machinable but rather brittle. Magnetic properties are developed by reheating for approximately 90 min at about 1250 F after the solution heat treatment.

The Alnico alloys cannot be worked hot or cold. Magnets are produced by casting and grinding. Drilling, tapping and such processes can be performed only with the aid of soft inserts in the castings. Heat treatment consists of a solution treatment between 1900 and 2100 F, air-cooling, and then aging for approximately an hour at about 1100 to 1300 F. Small magnets may require a slower rate of air cooling and heavy ones may require accelerated cooling in an air blast to develop the desired properties. Rapid cooling favors high values of B_r and slow cooling, high values of H_c. The heat treatment for Alnico 5 is an exception in that the solution temperature is about 2400 F and the aging treatment consists of holding for 4 to 10 hr at 1000 to 1150 F. Alnico 5, which is highly directional

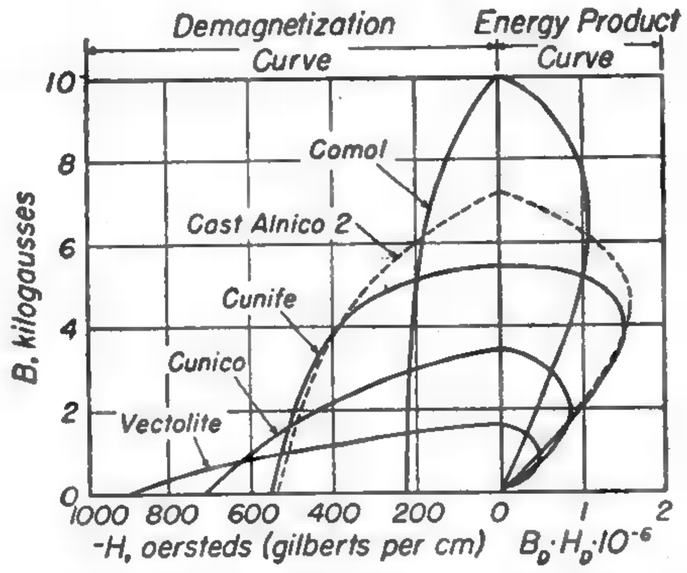

Fig. 7 Demagnetization curves and energy product curves of various magnet alloys

magnetically, requires cooling from the solution temperature in a magnetic field oriented to conform to the pattern of magnetization desired in the finished magnet. Suppliers of Alnico magnets customarily furnish them ground to size, heat treated and magnetized.

Cunife, Cunico and Silmanal are ductile alloys that can be produced in a wide variety of designs by forming, drawing, punching or machining. Cunife is directional and should be magnetized in the direction of cold working. In sheet form this alloy has properties considerably below those of other wrought forms.

Vectolite and sintered Alnico magnets are made from powdered oxides or metals pressed in a die to approximately the final shape and size, and sintered. Both can be ground to final size if very close tolerances are desired, but Vectolite is mechanically weak and is preferably sintered to final size. Vectolite is an electrical nonconductor. Sintered Alnico is fine-grained and stronger mechanically than cast Alnico. The chief advantage of sintered Alnico lies in the production of small sizes and intricate shapes.

Vicalloy is a ductile material with magnetic properties somewhat better than Comol or 36% Co steel. The chief use of Vicalloy has been in magnetic recorder tape.

Comol or Remalloy, Vicalloy, and the platinum-cobalt alloy are not commercially available at present (1947).

Curves of demagnetization and energy product for the magnet alloys are shown in Fig. 5, 6, 7 and 8.

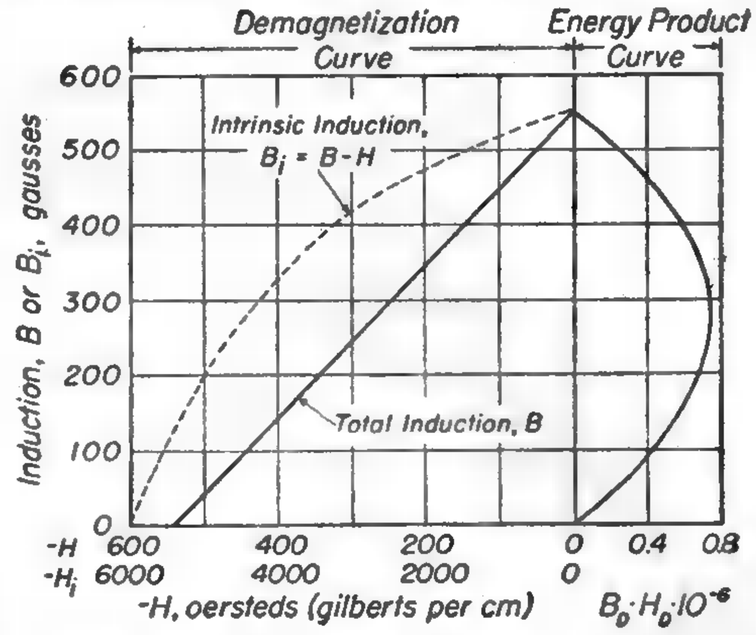

Fig. 8 Demagnetization curves of intrinsic induction and total induction and energy product curve for Silmanal

Iron-Nickel Alloys

By J. W. Sands*

IRON and nickel are soluble in all proportions in the molten state and form solid solutions during solidification. At room temperature the alloys may be either ferritic or austenitic in structure, depending on the nickel content and, in some instances, on the thermal history of the sample. Additions of carbon also affect the phase relationships. Nickel lowers progressively the temperature of the gamma-to-alpha transformation in iron, imparts a considerable hysteresis in the temperature of the occurrence of this transformation during heating and cooling, and introduces a considerable spread between the temperatures of the beginning and end of transformation. The lowering of the transformation range is so pronounced that when the nickel content is about 34%, the transformation cannot be reached, even at the temperature of liquid hydrogen (20 C above absolute zero). Hence, all the alloys containing more than this amount of nickel are austenitic (face-centered cubic) under all conditions.

Alloys of lower nickel content may be either ferritic or austenitic or a mixture of both, depending on the thermal

* Development and Research Division, The International Nickel Company, Inc., New York

history of the sample. Alloys that are not wholly austenitic at room temperature are considered to be steels, and are therefore outside the scope of this article. They are discussed in the article "Nickel in Steel", page 473.

Fig. 4 Variation of specific heat in cal per ■ per °C with nickel content in iron-nickel alloys (Ingersoll)

The iron-nickel system includes alloys that have unusual thermal expansion, magnetic and thermoelastic characteristics; these properties are used to advantage in a number of alloys for special purposes. Thermal expansion over an appreciable range of temperature becomes virtually negligible in the vicinity of 36% Ni, but increases in compositions that contain more nickel and less nickel. Thus in the range of composition between 30 and 60% Ni, it is possible to select alloys of appropriate expansivity to fit particular applications. These alloys are used for a wide variety of applications including precision variable condensers for radio apparatus, alloys for sealing glass (often with the addition of cobalt or chromium), and material for the low-expansion side of thermostatic bimetal. The high-expansion side also is frequently an alloy with an iron-nickel base and an addition of chromium. A favored composition is 22% Ni and 3% Cr. The low-expansion alloys are discussed in detail in the article beginning on page 601.

Most metals possess a negative thermal coefficient of the elastic modulus; that is, they lose stiffness with increasing temperature. Iron-nickel alloys with nickel between about 27 and 44% exhibit positive coefficients, reaching a rather high maximum at about 36%, which is also the point of minimum thermal expansion. The coefficient of elastic modulus is of value for certain applications involving temperature compensation. Composite springs of steel and 36% Ni-Fe can be made to maintain a constant stiffness regardless of fluctuations in temperature, because of the opposing effects of temperature on the moduli of the two materials.

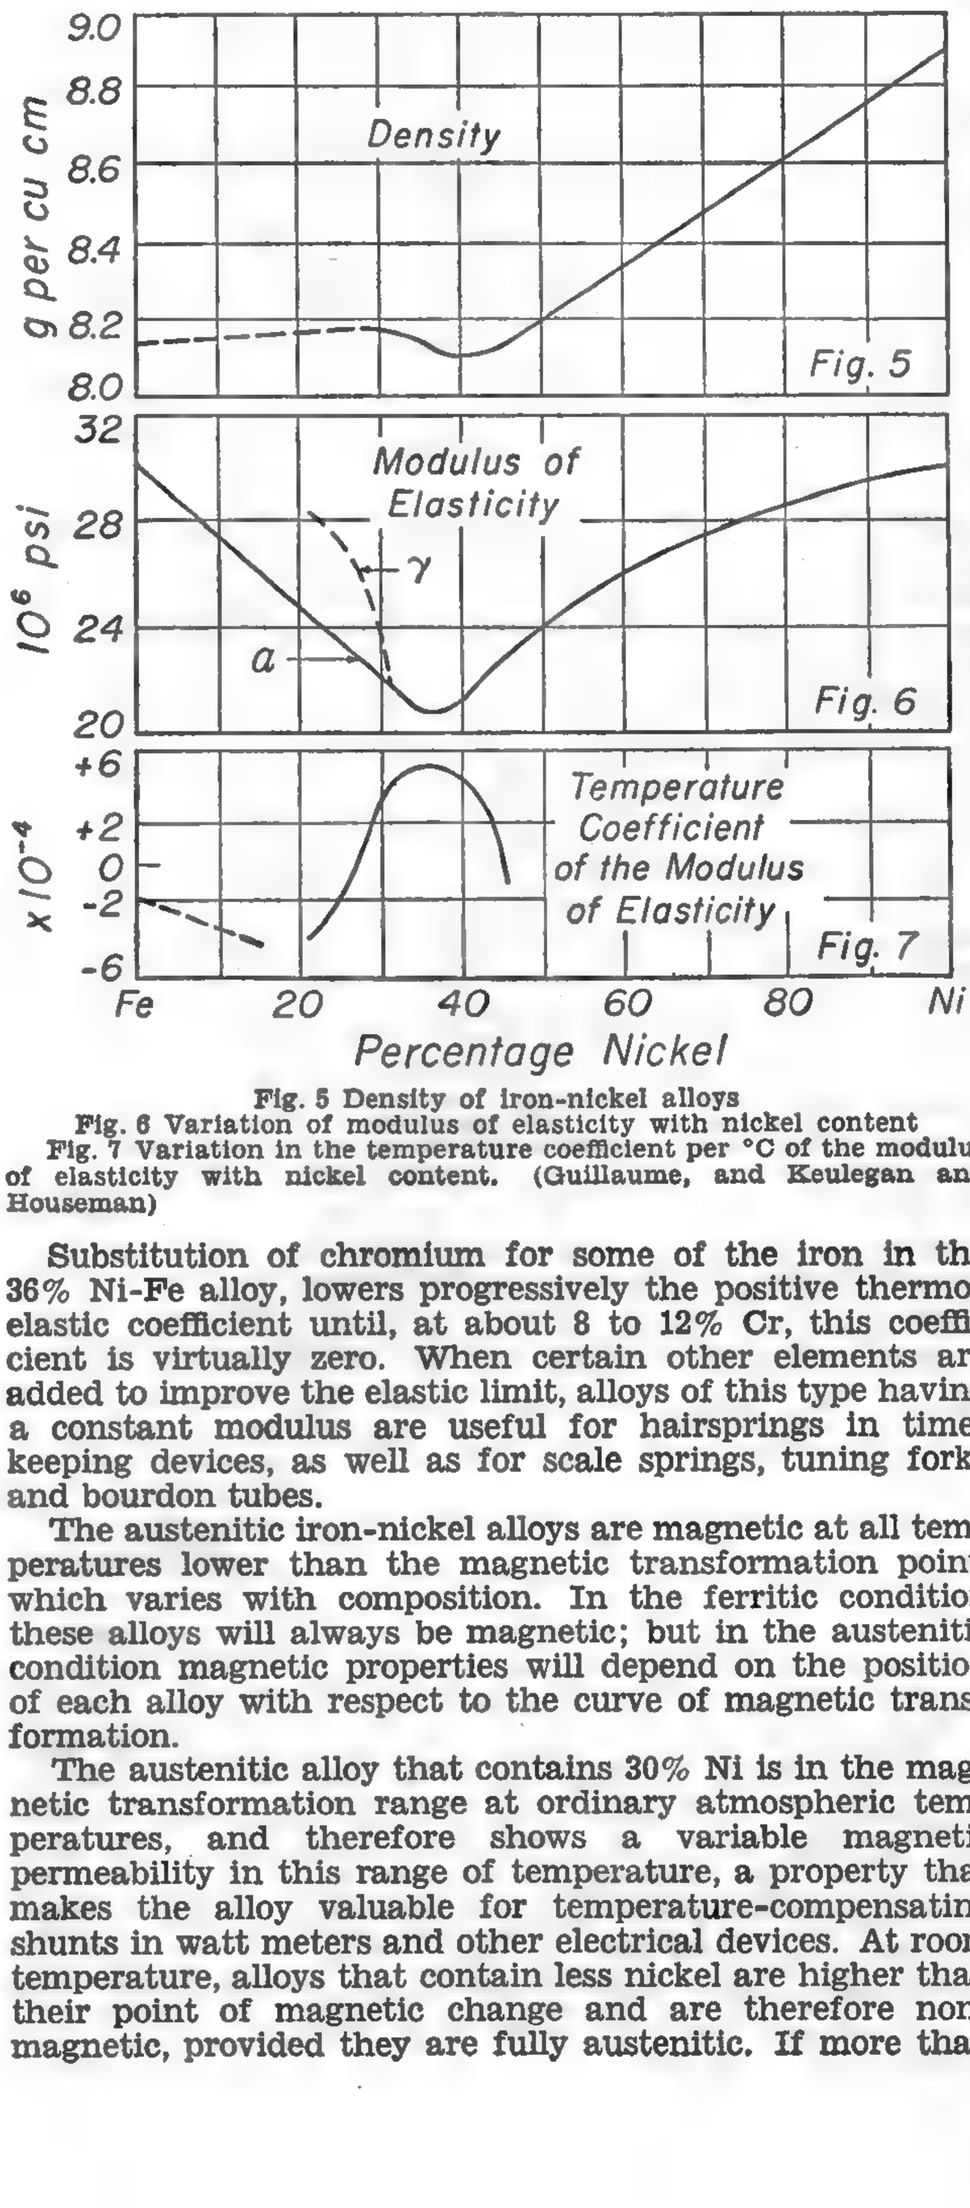

Fig. 5 Density of iron-nickel alloys

Fig. 6 Variation of modulus of elasticity with nickel content

Fig. 7 Variation in the temperature coefficient per °C of the modulus of elasticity with nickel content. (Guillaume, and Keulegan and Houseman)

Substitution of chromium for some of the iron in the 36% Ni-Fe alloy, lowers progressively the positive thermoelastic coefficient until, at about 8 to 12% Cr, this coefficient is virtually zero. When certain other elements are added to improve the elastic limit, alloys of this type having a constant modulus are useful for hairsprings in timekeeping devices, as well as for scale springs, tuning forks and bourdon tubes.

The austenitic iron-nickel alloys are magnetic at all temperatures lower than the magnetic transformation point, which varies with composition. In the ferritic condition these alloys will always be magnetic; but in the austenitic condition magnetic properties will depend on the position of each alloy with respect to the curve of magnetic transformation.

The austenitic alloy that contains 30% Ni is in the magnetic transformation range at ordinary atmospheric temperatures, and therefore shows a variable magnetic permeability in this range of temperature, a property that makes the alloy valuable for temperature-compensating shunts in watt meters and other electrical devices. At room temperature, alloys that contain less nickel are higher than their point of magnetic change and are therefore nonmagnetic, provided they are fully austenitic. If more than

20% Ni is present, air cooling is sufficiently rapid to suppress the change from gamma to alpha phase; therefore these alloys are useful for applications requiring nonmagnetic metals of good strength, high toughness and favorable resistance to corrosion. For reasons of economy, however, the usual practice is to reduce the nickel content and restore the stability of austenite by additions of manganese and chromium.

(a) Data from Ingersoll, Phys Rev, 16, 126 (1920)
(b) For specific resistance, see Fig. 2.

In the range of stable austenitic iron-nickel alloys that contain from 35 to 90% Ni, a number of alloys have been developed that possess extremely useful magnetic characteristics. One of the important properties of these materials is high permeability under the influence of weak magnetic fields, making them valuable as loading materials in electrical communication circuits. As a class, these alloys show high permeability and low hysteresis loss. By variation in the percentage of nickel and judicious additions of other elements, such as cobalt, copper, molybdenum, and chromium, various characteristics can be emphasized and different combinations of magnetic properties can be secured. Molybdenum and chromium are particularly useful in increasing the electrical resistivity, thus reducing eddy-current losses. Further details are given in the article "Magnetically Soft Materials", page 587.

Thus alloys in the iron-nickel series vary all the way from the completely nonmagnetic to those offering maximum softness. It is interesting to note that additions of aluminum to appropriate iron-nickel alloys promote the opposite extreme, high magnetic hardness. Such alloys are now used extensively for permanent magnets, since they provide more magnetic energy per unit of volume than any other permanent magnet material commercially available. They are made in several grades; some contain various combinations of cobalt, titanium and copper, in addition to the nickel and aluminum.

Variations, with nickel content, of some of the important physical and mechanical properties of the iron-nickel series are shown in Table I and Fig. 1 to 7.

Since the iron-nickel alloys are austenitic, they can be hardened only by cold work. This is sometimes a disadvantage when high elastic properties are desired in spring materials that have a constant modulus and in thermostatic bimetal. Recently it has been found that additions of titanium and aluminum make these alloys precipitation-hardenable.* Heat treatment plus cold work is even more effective.

Data concerning the properties of these hardenable alloys are included in the next article in this Handbook.

Low-Expansion Alloys

By M. A. Hunter*

ALLOYS of iron and nickel have many anomalous properties, depending on the relative proportions of the two elements in the alloy. Guillaume discovered the alloys of low coefficient of linear thermal expansion. In an intensive investigation of a series of various compositions, he found coefficients of linear expansion ranging from a small negative value (-0.5×10^{-6} per °C) to a large positive value (20×10^{-6} per °C). The alloy containing 36% Ni with minor amounts of manganese, silicon and carbon, amounting to less than 1% in all, had a coefficient of expansion so low that its length was almost invariable for ordinary changes in temperature. For this reason Guillaume gave the alloy the name "Invar".

Subsequently in the work of Guillaume and Chevenard an intensive study was made of the thermal and elastic properties of this class of alloys. Alloys with higher contents of nickel were found to possess higher coefficients of expansion. The alloy containing 39% Ni had a coefficient of expansion corresponding to that of the low-expansion glasses. The 46% alloy had a coefficient equivalent to that of platinum (9.0×10^{-6} per °C) and received the name "Platinite". A 42% Ni alloy, when covered with copper to prevent gassing at the seal, is known as "Dumet wire" and is used to replace platinum as the "seal-in" wire in incandescent lamps and vacuum tubes. The 56% alloy has a coefficient approaching that of ordinary steel (11×10^{-6} per °C). Nilvar is identical with Invar (36% Ni).

While studying the elastic properties, Guillaume disclosed the alloy Elinvar, containing 36% Ni and 12% Cr and having an invariable modulus of elasticity over a considerable range of temperature, as well as low thermal expansivity.

Alloys that contain less than 36% Ni have much higher coefficients of expansion. The 18% Ni alloy has an expansion coefficient of 20×10^{-6} per °C. These alloys are of the so-called "irreversible" type and, by reason of their high coefficients, are excluded from the present discussion.

It has been found that certain percentages of cobalt can be used with advantage to replace nickel in the 36% alloy. Substitution of 5% Co for 5% Ni gives an alloy with a coefficient even lower than that of Invar, and less susceptible to variations in heat treatment.

Effect of Composition on Expansivity. The effect of variations in nickel content on the linear expansivity is shown in Fig. 1.

The minimum expansivity occurs at about 36% Ni. Minor additions of other metals have a considerable influence on the position of this minimum expansivity. The effect of additions of manganese, chromium, copper or carbon is shown in Fig. 2.

Minimum expansivity is shifted toward higher contents of nickel when manganese or chromium is added and toward lower contents of nickel when copper or carbon is

* Consulting Engineer, Driver-Harris Company, Harrison, N. J., and Head, Department of Metallurgical Engineering, Rensselaer Polytechnic Institute, Troy, N. Y.

added. The minimum expansivity for any of these ternary alloys is, in general, greater than that of a typical Invar (Fig. 2).

Additions of silicon, tungsten or molybdenum produce effects similar to that of manganese or chromium; the

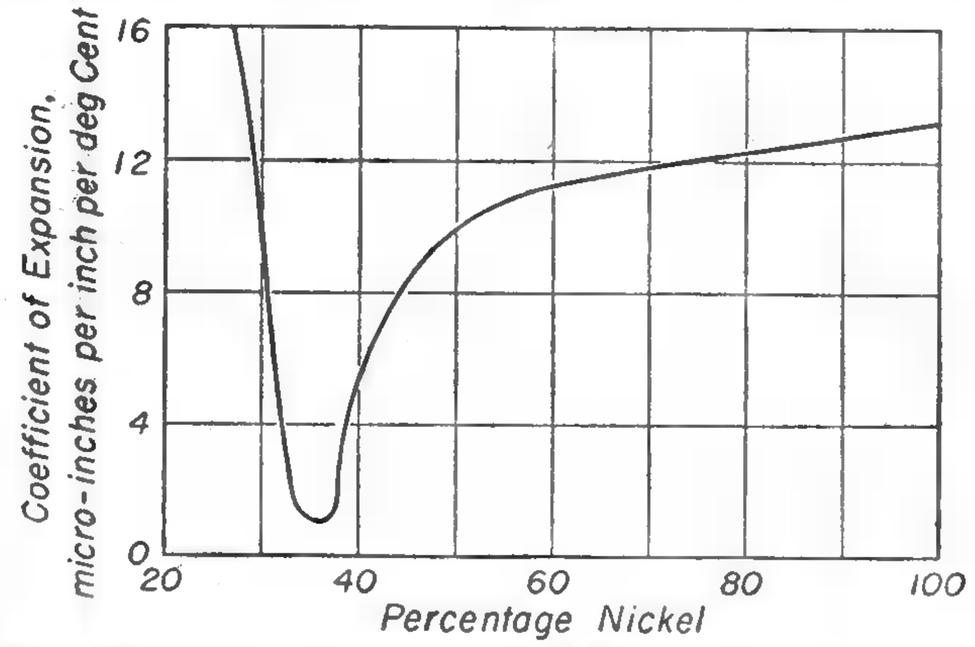

Fig. 1 Effect of nickel on the coefficient of linear thermal expansion of iron-nickel alloys at 20 C (0.4% Mn, 0.1% C) (Guillaume)

composition of minimum expansivity is shifted toward higher contents of nickel.

Carbon is said to produce instability in Invar. Guillaume attributes this to the changing solubility in the austenitic matrix during heat treatment.

Expansivity. It is not generally recognized that the low

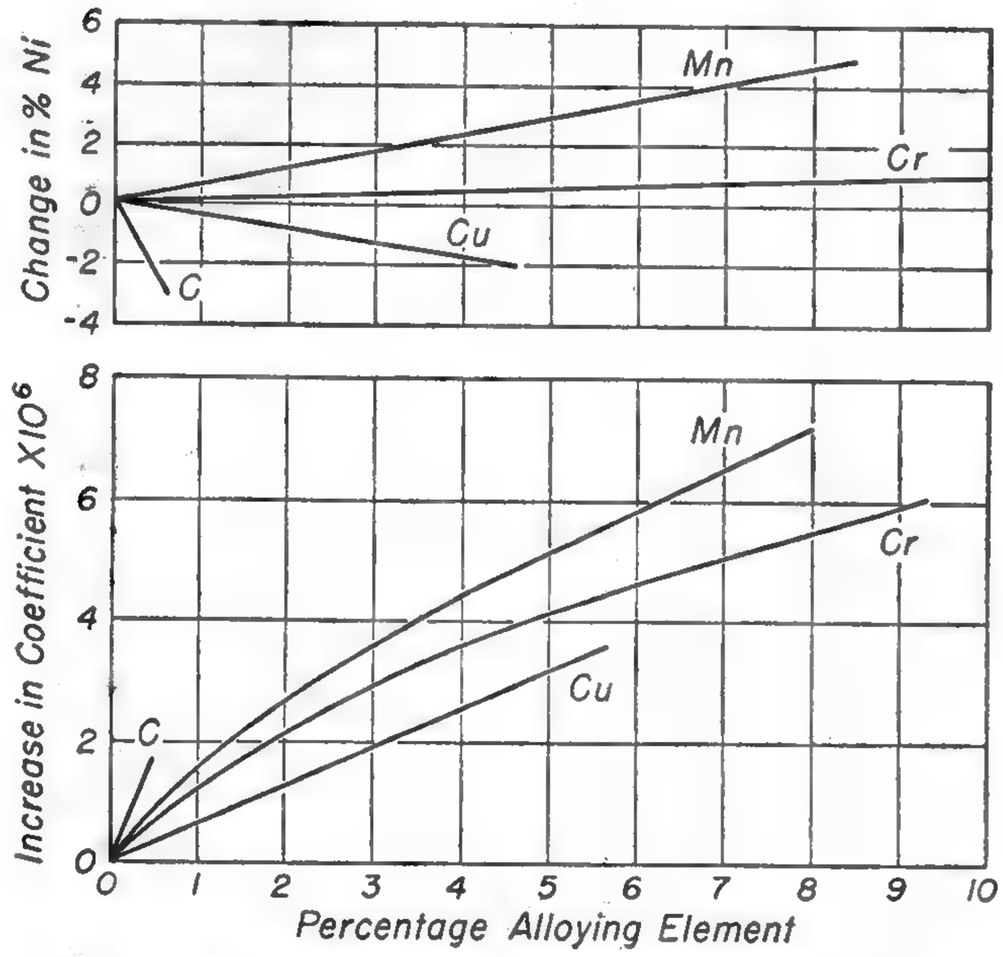

Fig. 2 Effect of alloying elements on the expansion characteristics of iron-nickel alloys. (*Upper*) Displacement of the nickel content of alloy of minimum expansivity caused by additions of manganese, chromium, copper, and carbon. (*Lower*) Change caused in the value of minimum coefficient of expansion by additions of manganese, chromium, copper, and carbon (Guillaume)

expansivity of Invar and related alloys is applicable over a rather narrow range of temperature. At low temperatures, in the region from *A* to *B* (Fig. 3) the coefficient of expansion is high. In the interval between *B* and *C* the coefficient decreases, reaching a minimum in the region from *C* to *D*. With increasing temperature, the coefficient begins again to increase in the range from *D* to *E*, and thereafter (from *E* to *F*) the expansion curve follows a trend somewhat similar to that of the nickel or iron of which the alloy is composed. It is clear that the minimum expansivity prevails only in the range from *C* to *D*.

Between *D* and *E* the coefficient is changing rapidly to a higher value. The temperature limits for a *well-annealed* 36% Ni iron alloy are 162 and 271 C. These temperatures correspond to the initial and final loss of magnetism in the material. The slope of the curve between *C* and *D* is then

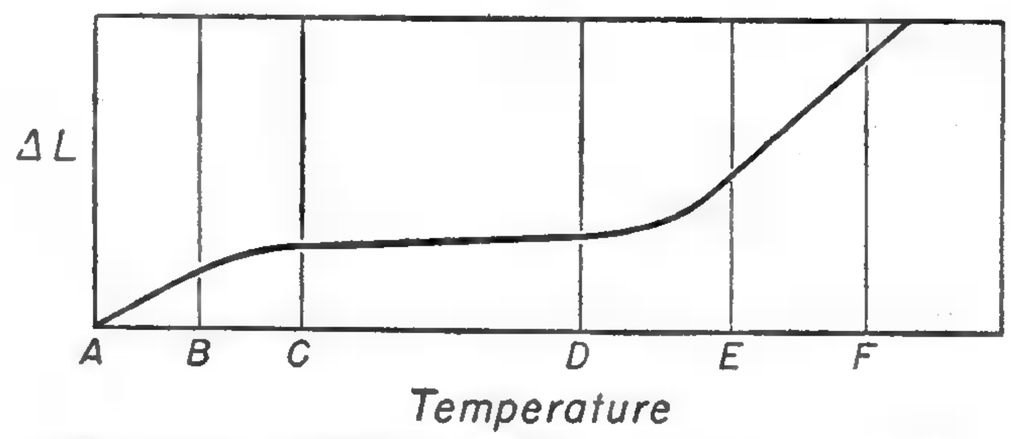

Fig. 3 Change in length (ΔL) with temperature (T) of a typical Invar (Guillaume)

a measure of the coefficient of expansion over a limited range of temperature. The data in Table I are given by Guillaume for the coefficient of linear expansion between 0 and 38 C.

Over wider ranges of temperature, the behavior of the alloys is represented by the curves of Fig. 4. For comparison, the curve of length versus temperature for an ordinary steel is included.

Heat treatment or cold work changes the expansivity of Invar (or Nilvar) considerably. The effect of heat treatment is shown in Table II by Russell. The expansivity is

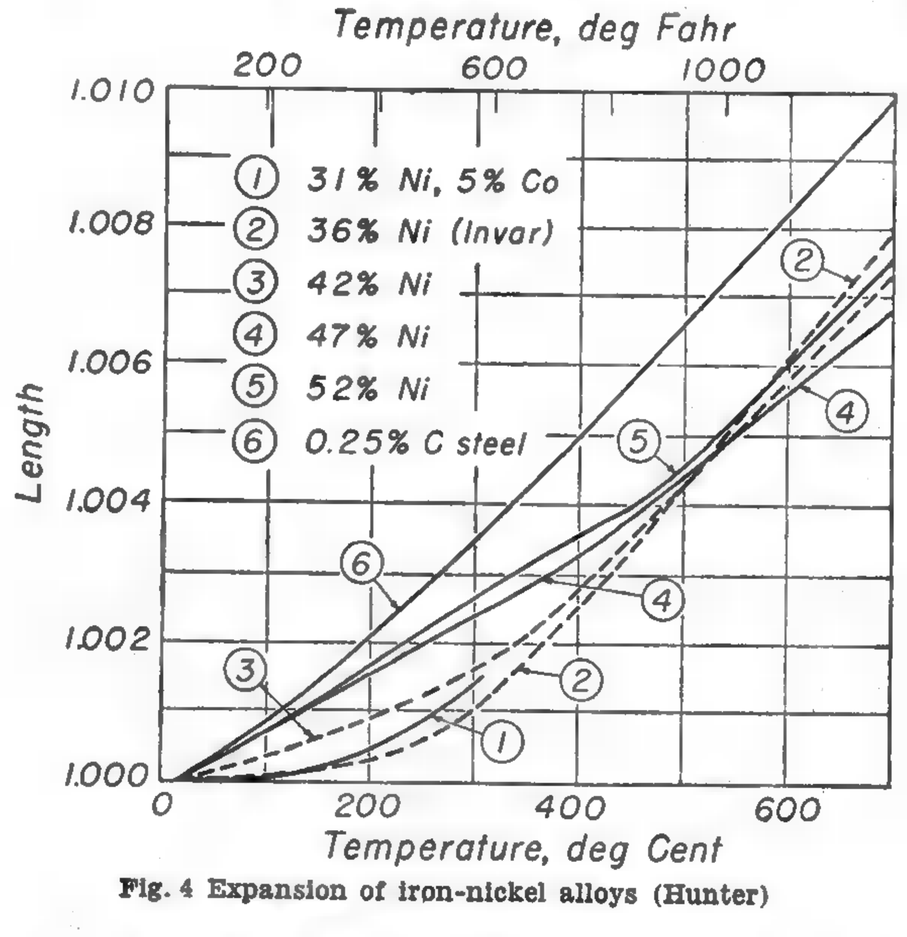

Fig. 4 Expansion of iron-nickel alloys (Hunter)

greatest in well-annealed material and least in the quenched samples.

Cold drawing also decreases the expansivity. The values for the coefficient in Table III are from experiments by the author on two heats of Nilvar (Invar).

By cold work after a quenching operation it is possible to produce material with a zero coefficient of expansion or even a negative one. A negative coefficient may be increased to zero by careful annealing at a low temperature. All these artificial methods of securing a low coefficient produce instability in the material. With lapse of time and variation in temperature, the low coefficients will usually recede to the normal values for the material. This aging is responsible for the secular and transitory changes that take place in the material. Although these variations are important in special applications, such as geodetic tapes, they are of little significance in ordinary operations. For such special applications it is essential to stabilize the material by cooling it slowly from 100 to 20 C over a period of many months, followed by prolonged aging at room

temperature; but unless the material is to be used subsequently within the limits of the atmospheric variation in temperature, such stabilization is of no value.

Magnetic Properties. All iron-nickel alloys of the Invar class are magnetic at room temperature. They lose their magnetism at higher temperatures and become paramagnetic. The points of inflection in the curves of Fig. 4 indicate the loss of magnetism. For a true Invar (36% Ni) Russell found that, in a well-annealed sample, the loss of

Table I. Thermal Expansion of Iron-Nickel Alloys

% Ni	Mean Coefficient × 10^6 per °C	% Ni	Mean Coefficient × 10^6 per °C
31.4	$3.395 + 0.00885\,t$	43.6	$7.992 - 0.00273\,t$
34.6	$1.373 + 0.00237\,t$	44.4	$8.508 - 0.00251\,t$
35.6	$0.877 + 0.00127\,t$	48.7	$9.901 - 0.00067\,t$
37.3	$3.457 - 0.00647\,t$	50.7	$9.984 + 0.00243\,t$
39.4	$5.357 - 0.00448\,t$	53.2	$10.045 + 0.00031\,t$

magnetism began at 162 C and was complete at 271 C. In a quenched sample, the loss began at 205 C and was complete at 271 C.

Slow cooling through this range of temperature eliminates, to a large extent, the transitory and secular changes that are always troublesome in materials of this class.

Electrical Properties. The electrical resistivity of Invar is in the range from 75 to 85 microhm-cm at ordinary

Table II. Effect of Heat Treatment on the Coefficient of Expansion of Invar

Treatment	Mean Coefficient, × 10^{-6} per deg Cent	
After forging	17 to 100 C	1.66
	17 to 250 C	3.11
Quenched from 830 C	18 to 100 C	0.64
	18 to 250 C	2.53
Quenched from 830 C, tempered	15 to 100 C	1.02
	15 to 250 C	2.43
Cooled from 830 to room temperature in 19 hr	15 to 100 C	2.01
	15 to 250 C	2.89

temperatures. The temperature coefficient of electrical resistivity is of the order of 0.0012 per °C over the range of low expansivity. The thermoelectric power (against copper) is about 10 microvolts per °C.

Other Physical and Mechanical Properties. From various sources Sands has collected information on the miscellaneous properties of Invar, from which the data of Table

Table III. Effect of Quenching and Cold Drawing on the Expansivity of Invar per degree Centigrade

Direct from Hot Mill	Annealed and Quenched	Quenched and Cold Drawn 0.125 to 0.250 In.
1.4×10^{-6}	0.5×10^{-6}	0.14×10^{-6}
1.4×10^{-6}	0.8×10^{-6}	0.3×10^{-6}

IV are taken. The alloy was in the hot rolled or forged condition.

The effect of temperature on the mechanical properties is shown in Fig. 5.

Processing. Considerable care must be used in the hot working of these iron-nickel alloys, since they have a tendency to check and break up unless carefully handled. Invar and related alloys should be annealed in a reducing atmosphere. These alloys are susceptible to intercrystalline attack during annealing; therefore, the best results are usually obtained by annealing in an atmosphere that contains a large percentage of a neutral gas, such as nitrogen, and a small percentage of a reducing gas.

The cold rolling and drawing of these iron-nickel alloys is quite similar to that of nickel.

Heat Treatment of Invar. Annealing between 750 and 850 C (1380 and 1560 F) gives good results. When the alloy is quenched in water from these temperatures, the expansivity of the material is decreased, but instability is induced both in actual length and in coefficient of expansion. To overcome these defects and to stabilize the wire, an anneal is necessary at a low temperature (200 to 300 F) followed by slow cooling to room temperature over a period of months. Slow cooling through the magnetic transformation has also been found satisfactory.

Table IV. Some Physical and Mechanical Properties of Invar

Solidus temperature	1425 C (2600 F)
Density	8.0 ■ per cu cm (500 lb per cu ft)
Tensile strength	65,000 to 85,000 psi
Yield point	40,000 to 60,000 psi
Elastic limit	20,000 to 30,000 psi
Elongation	30 to 45%
Reduction in area	55 to 70%
Scleroscope hardness	19
Brinell hardness	160
Modulus of elasticity in tension	21,400,000 psi
Thermoelastic coefficient	500 × 10^{-6} per °C
Specific heat (25 to 100 C)	0.123 cal per ■ per °C
Thermal conductivity (20 to 100 C)	0.0262 cgs units
Thermoelectric power (against copper) (minus 96 C)	9.8 microvolts per °C

Applications. Invar is used for absolute standards of length; rods and tapes for geodetic work; compensating pendulums and balance wheels in clocks and watches; elements in moving parts where control of expansion is necessary as in automobile pistons; and thermostatic strip.

Other Iron-Nickel Alloys. Alloys of iron and nickel that contain more nickel than Invar, retain to some extent the expansion characteristics of Invar.

Since further additions of nickel raise the temperature at which the inherent magnetism of the alloy disappears, the inflection temperature in the expansion curve rises with the increasing nickel content. Although this increase in range is an advantage in some circumstances, it is obtained at a sacrifice of the low coefficient of expansion.

Scott[3] has published information on the coefficient of expansion of iron-nickel alloys up to the inflection tem-

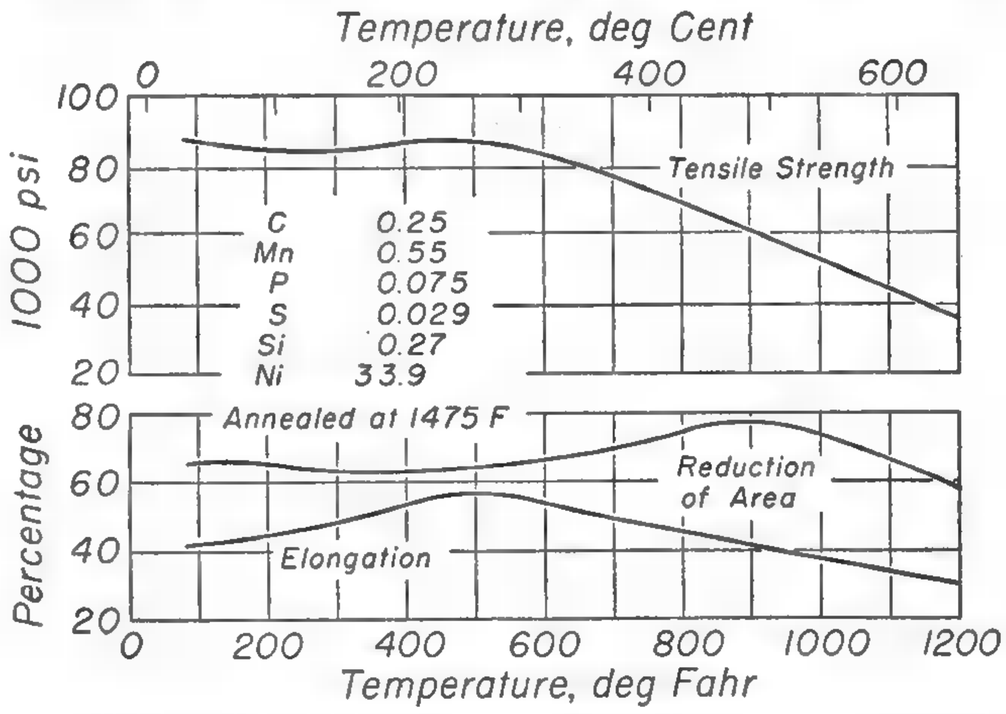

Fig. 5 Effect of temperature on the mechanical properties of forged 34% Ni iron-nickel alloys (MacPherran)

perature. Lohr and Hopkins[5] give data on a more extended range of nickel contents up to 68%, as presented in Table V and Fig. 6.

Special Alloys. Certain ternary alloys that contain nickel and iron are interesting by reason of their special properties.

Super Nilvar. The replacement of some of the nickel by cobalt in an alloy of the Invar composition results in a lowering of the linear coefficient of expansion of the alloy. An alloy containing 31% Ni and 4 to 6% Co, has a zero coefficient of expansion in the hot rolled condition. Annealing and quenching appear to raise the coefficient somewhat, but in general the coefficient obtained from these alloys is lower than that obtained from Invar unless it is subjected to cold work. An extensive investigation of this class of alloys has been made by Masumoto.[1]

Fe-Ni-Co Alloys. Scott[3] has investigated the expansion properties of a series of low-expansion Fe-Ni-Co alloys

over a range of cobalt additions as high as 40%. Such additions increase the coefficient of expansion at room temperature, but since they also raise the inflection temperature, they produce an alloy with a moderately low coefficient of expansion over a wider range of temperature.

Table V. Expansion Characteristics of Iron-Nickel Alloys

Composition, % Mn	Si	Ni	Inflection Temperature,(a) deg Cent	Average Coefficient of Expansion to Inflection Temp, × 10⁻⁶ per deg Cent

0.18	0.04	64.87.....	...	13.62
0.00	0.05	67.98.....	...	14.37

(a) Note that in alloys containing more than 55% Ni, the inflection temperature is not in evidence.

Scott expresses his observations in the form of equations. If θ is inflection temperature in degrees Centigrade, X the nickel content, Y the cobalt content, Z the manganese content and W the carbon content, the inflection temperature of any alloy in the group studied is given by:

$$\theta = 19.5\,(X + Y) - 22Z - 0W - 465$$

Introducing the restriction that the nickel and iron contents shall be so related as to depress the Ar_3 point to about minus 100 C, then:

$$Y = 0.0795\theta + 4.8Z + 19W - 18.1$$
$$X = 41.9 - 0.0282\theta - 3.7Z - 19W$$

for inflection temperatures between 200 and 600 C.

Table VI. Minimum Coefficient of Expansion in Relation to Nickel and Titanium Contents

Percentage Ti	Optimum Ni	Coefficient of Expansion, × 10⁻⁶ per °C
0	36.5	1.4
2	40.0	2.9
3	42.5	3.6

The expansivities obtainable with these compositions are given by:

$$a_1 \times 10^6 = 0.024\theta + 0.38Z - 1.2W - 6.65$$
$$a_2 \times 10^6 = 0.024\theta + 0.38Z - 1.2W - 5.6$$

The former represents minimum expansivity and the latter mean expansivity when θ is between 350 and 600 C.

Applications of these alloys for sealing wires in glass are given by Scott[4] and by Hull and Burger.[5] Scott's alloy "Kovar" and Hull's alloy "Fernico" contain approximately 54% Fe, 28% Ni, and 18% Co.

Fe-Co-Cr Alloys. Masumoto[2] has studied an alloy containing 36.5 to 37% Fe, 53 to 54.5% Co, and 9 to 10% Cr, which has an exceedingly low coefficient of expansion, at times negative over the range from 0 to 100 C. An alloy in this class is suggested by Hull as a seal-in wire in special glasses, "Fernichrome", containing 37% Fe, 30% Ni, 25% Co and 8% Cr.

Elinvar. In determining the thermoelastic coefficients of iron-nickel alloys, Guillaume found that Invar has the highest elastic coefficient of all the alloys in the related group. However, two alloys at 29 and 45% Ni have zero thermoelastic coefficient; that is, the modulus of elasticity does not change with variations in temperature. But since, in these alloys, small variations in the nickel content produce large variations in the thermoelastic coefficient, the

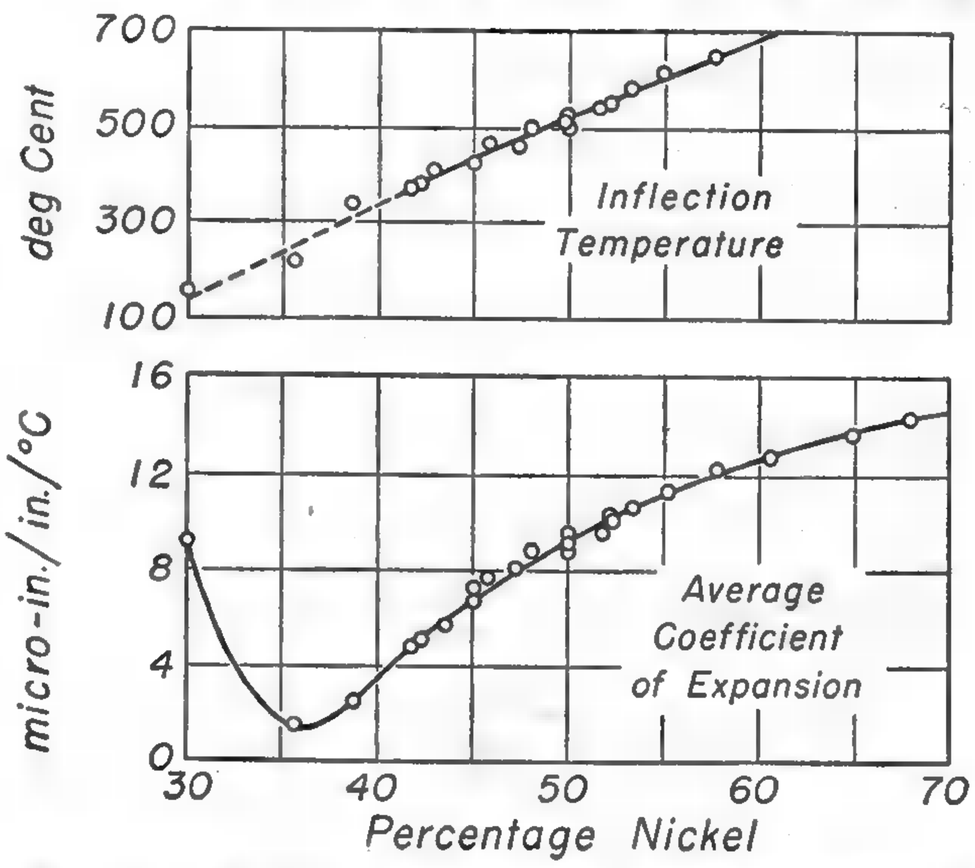

Fig. 6 Effect of nickel content on the expansion characteristics of iron-nickel alloys. (*Upper*) **Effect on the inflection temperature.** (*Lower*) **Effect on the average coefficient of expansion between room temperature and the inflection temperature**

commercial application of the discovery has been a difficult one. Guillaume found that the addition of 12% Cr to an alloy containing 36% Ni produces an alloy that has zero thermoelastic coefficient without susceptibility to small variations in nickel content, which are to be expected in commercial melting. This alloy was named "Elinvar".

Elinvar has a particular application in the construction of such articles as hairsprings and balance wheels in clocks and watches, and in tuning forks used in radio synchronization where an invariable modulus of elasticity is required. This alloy has the further advantage of being comparatively rustproof.

The composition of this material has been somewhat modified from the original specifications. Shubrooks gives the following limits for the material as now used:

Nickel	33 to 35%	Manganese	0.5 to 2%
Iron	61 to 53%	Silicon	0.5 to 2%
Chromium	4 to 5%	Carbon	0.5 to 2%
Tungsten	1 to 3%		

Hardenable Alloys. Alloys of the type having a low coefficient of expansion and those having a constant modulus of elasticity can be made age hardenable by additions of titanium.[12,13,14]

In alloys of the low-expansion type, the nickel content

Table VII. Mechanical Properties of Iron-Nickel Alloys with 2.4% Ti, 0.06% C

Condition	Yield Strength (0.2% offset), psi	Tensile Strength, psi	Elong, % in 2 in.	Bhn
42% Ni, Inflection Temperature 220 C, Min Coefficient Expansion 3.2 × 10⁻⁶ per °C				
Solution treated.....	40,000	90,000	32	140
Solution treated and age hardened..	120,000	165,000	14	330
Solution treated, cold rolled 50% and age hardened..	165,000	195,000	5	385
52% Ni, Inflection Temperature 440 C, Min Coefficient Expansion 9.5 × 10⁻⁶ per °C				
Solution treated.....	35,000	85,000	27	125
Solution treated and age hardened..	95,000	120,000	17	305

must be increased, as shown in Table VI, when titanium is added, since any titanium that has not combined with the carbon content of the alloy, will neutralize more than twice its own weight of nickel by forming an intermetallic compound during the hardening operation.

Table VIII. Thermoelastic Coefficients of Fe-Ni-Cr-Ti Alloys

Composition, % Ni	Cr	C	Ti	Thermoelastic Coefficient × 10^6, per °C	Possible Variation by Heat Treatment
42	5.4	0.06	2.4	0	+ 18 to − 23
42	6.0	0.06	2.4	+ 36	+ 54 to + 13
42	6.3	0.06	2.4	− 36	− 18 to − 60

The addition of titanium (1) raises the lowest attainable rate of expansion, (2) raises the nickel content at which the minimum occurs, and (3) lowers the inflection temperature.

Mechanical properties of alloys containing 2.4% Ti and 0.06% C are given in Table VII.

In alloys of the constant-modulus type, the titanium additions can be used to control the thermoelastic coefficient by variation in heat treatment. The three compositions listed in Table VIII cover the usual range.

Recommended solution treatment for the alloys that contain 2.4% Ti is 950 to 1000 C for 20 to 90 min, depending on size. Recommended duration of aging varies from 48 hr at 600 C to 3 hr at 730 C for solution-treated material and from 4 hr at 600 C to 1 hr at 730 C for material that has been solution-treated and subsequently cold worked 50%.

Table IX. Mechanical Properties of a Constant-Modulus Alloy Containing 42% Ni, 2.4% Ti, 5.4% Cr

Condition	Yield Strength, psi	Tensile Strength, psi	Elong, % in 2 in.	Bhn	Modulus of Elasticity, million psi
Solution treated.....	35,000	90,000	40	145	24
Solution treated and aged 3 hr at 730 C	115,000	180,000	18	345	26.5
Solution treated and cold worked 50%.	130,000	135,000	6	275	25.5
Solution treated, cold worked 50% and aged 1 hr at 730 C....	180,000	200,000	7	395	27

Table IX lists the mechanical properties of a constant-modulus alloy containing 42% Ni, 2.4% Ti and 5.4% Cr.

Engineering Applications. The use of alloys that have low coefficients of expansion has been confined mainly to such applications as geodetic tape, bimetal strip, and glass-to-metal seals. Newer applications appear in the electronic and radio fields.[15] Variable condensers are built almost entirely of Invar. Struts used on jet engines are made of Invar to ensure rigidity with temperature changes. Contact tabs of 47% Ni alloy, used in electrical resistors, match the expansion characteristics of the enamel.

Where exacting specifications call for definite and invariable properties, these alloys with low coefficients of expansion are being made by powder metallurgy.

Machining Properties. Where free-machining is desirable, the addition of 0.25% Se to the alloy produces satisfactory results.

Ferrous Alloys Containing from 3 to 20% Aluminum

By Kent R. Van Horn*

ALUMINUM is added to certain ferrous alloys in appreciable quantities to improve the electrical and magnetic properties or the resistance to oxidation. The aluminum additions ranging from 3 to 20% exceed the quantities used for the nitriding steels or irons and for the deoxidation of steel. The alloys may be classed according to two general types of application—electrical and heat resistance.

Permanent Magnet Alloys Containing Aluminum. The improvement of the magnetic properties of iron or steel by aluminum is generally recognized. The beneficial influence of aluminum, like that of silicon, on magnetic permeability is indirect; that is, aluminum influences permeability beneficially through its effect on carbon, oxygen and perhaps other elements, although directly aluminum would probably affect pure iron adversely. Except for carbon in solution, aluminum and silicon, more than any other elements, increase the resistivity of iron, a property very important in a-c circuits.[1] The specific electrical resistance of iron is increased by 12 microhm-centimeters for each per cent of aluminum up to 3%. The electrical resistance of the 3½% Al composition is slightly less than that of the 3 to 4½% Si type. However, with the same method of preparation (vacuum melting), the silicon alloys are characterized by brittleness, while the 3½% aluminum iron has considerable ductility. There are some electrical installations where the aluminum-iron alloy has replaced the less expensive silicon types because the comparative brittleness of the iron-silicon alloys was undesirable. In general, aluminum has never become a serious competitor of silicon, because of difficulties encountered in manufacturing processes.

In 1934, patents were granted describing alloys containing aluminum and intended for permanent magnets. An iron alloy (Alnico) containing 10 to 20% Al, 20% Ni, 5% Co, and no carbon, has qualities surpassing those of the 30% cobalt-tungsten permanent magnet type.[2] The exceptional properties of this material have been utilized in an expanding field of magnetic applications.

Electrical Resistor Alloys. A series of electrical resistors containing iron, chromium and aluminum, is marketed as Alcres, Ohmax,[3] and Megapyr.[4] An alloy containing about 20% Cr, 5% Al, and the remainder iron, has a specific resistivity of 800 ohms per circular mil ft. If the aluminum content is increased to 10%, the material has a specific resistivity of 1000 ohms per circular mil ft. The value for a common nickel-chromium resistor is 650 ohms. The alloys containing aluminum also have excellent resistance to oxidation at elevated temperatures. These two qualities, and a lower density than the nickel-chromium type, are utilized for applications where large total resistances are required for a minimum space, as in radio resistors. The alloys are

* Chief, Cleveland Research Division, Aluminum Research Laboratories, Aluminum Company of America

more difficult to fabricate but can be produced in diameters as small as 1 mil for radio wires.

There is another group of resistors similar in composition and properties, except that cobalt is added. This Kanthal series[5] has about 25% Cr, 5% Al, 3% Co, and the remainder almost pure iron. The electrical resistance ranges from 810 to 875 ohms per circular mil ft. The density is lower than that of the nickel-chromium resistors, being 7.15 as compared with 8.35 g per cu cm. When fabricated from these metals, ribbons or wires of the standard sizes are recommended for use at temperatures from 2000 to 2450 F, because of the superior resistance to oxidation. However, the tensile strength is low at elevated temperatures, so it is necessary to provide suitable supports for the elements in the installation.

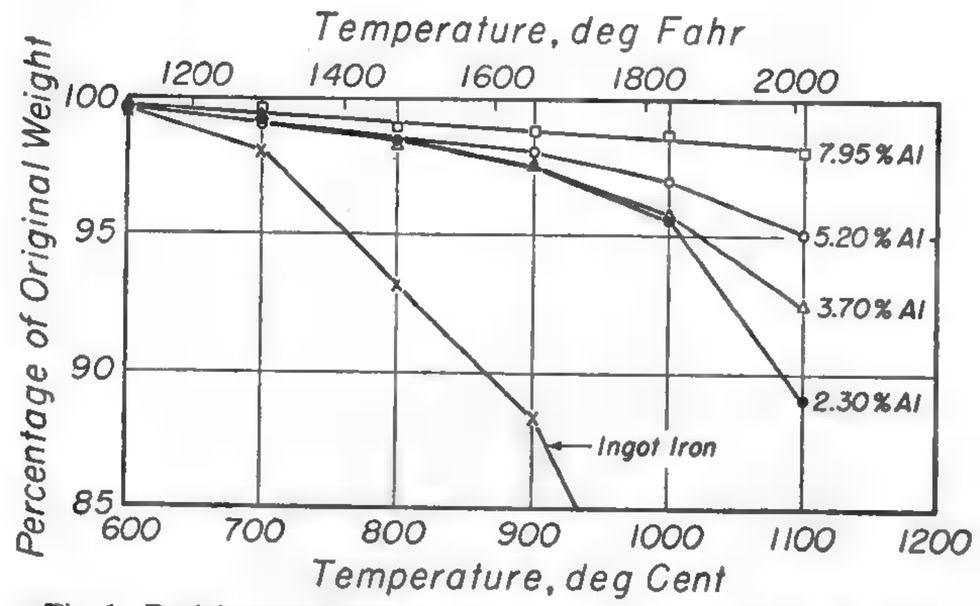

Fig. 1 Resistance of iron-aluminum alloys to oxidation at elevated temperature. Samples were held for two hours in air at the various constant temperatures, then ground to remove the oxidized surface, and the unoxidized portion was weighed. The alloys contained less than 0.01% C. Data for ingot iron are plotted for comparison. (N. A. Ziegler[8])

A third iron-base alloy[6] of this type is Smith Alloy No. 10. The chromium and aluminum contents, appreciably higher than in the first two groups, are 37.5% Cr, 7.5% Al, the remainder iron. The electrical resistance is 1000 ohms per circular mil ft and the density of the material is 6.9, so the volume is 22% greater than the volume of the same weight of the nickel-chromium type. The alloy can be hot formed into the required bends and helices. It is necessary to provide the correct type of nonsilica refractories and supports that allow for thermal expansion, growth and sagging of the elements. The three Fe-Cr-Al types are effective for high-temperature applications, such as furnaces for the heat treatment of high speed steel, heating steel for forging, and burning ceramic materials. These resistors also compete with the silicon carbide type in the higher part of their recommended temperature range.

Table I gives a comparison of some properties of iron-chromium-aluminum alloys and other materials used for electrical resistors.[13]

Iron-Aluminum Heat-Resisting Alloys. The outstanding resistance of iron-aluminum alloys to oxidation at elevated temperatures was reported in 1931 by Hauttmann.[7] The resistance to oxidation of the binary iron-aluminum alloys increases with the aluminum content from 4 to 9% Al (*see* Fig. 1[8]). In 1932 Ziegler[8] found that 4% Al when added to iron (vacuum melting) produced a forgeable alloy with good resistance to oxidation. Compared with the 80% Ni, 20% Cr type, alloys containing 6% Al have slightly inferior resistance to the softening effect of heat, but alloys containing 8% Al have superior resistance. These iron-aluminum alloys are forgeable to some extent and the presence of carbon has little effect on the resistance to scaling. The recognition of these characteristics has resulted in the development of a number of steels and irons containing aluminum.

The American Iron and Steel Institute has formulated specifications for a standard heat-resisting alloy, 406D, containing 12 to 14% Cr, 4.5% Al, 0.12% C, with the remainder iron. A well-known steel of this type is No. 1 JR. Castings and forgings are produced to a limited extent.

Alloys containing 7 to 15% Cr, 2 to 6% Al, and 1% C, are forgeable if the total aluminum and silicon content does not exceed about 5.5% with the silicon[9] about 1%. The steels may exhibit good resistance to oxidation at 1550 to 1850 F, depending on the total quantity of aluminum, chromium and silicon. These alloys have no wide application, because the beneficial properties can be procured more economically with silicon.

Aluminum has been added to the 18% Cr, 8% Ni stainless steel in quantities as large as 3%, to prevent scaling at high temperature and to increase machinability without impairing the other properties.[10,11] Modified casting alloys of this type containing aluminum have trade names of "Fahralloy" and "Hybnickel", with certain designating numbers.

High-silicon, high-aluminum cast irons constitute one of the four types of "refractory" cast irons widely used in Europe.[12] These alloys, containing 6 to 9% Si, 3 to 7% Al, have excellent resistance to oxidation but are not employed where high tensile strength is required. The silicon-aluminum cast irons are considerably cheaper than the other three common types of "refractory" irons.

Isothermal Transformation Diagrams of Steel

By E. S. Davenport*

WHEN a steel in the austenitic condition is held at any constant temperature below the range in which its austenite is stable, it will in time transform to the ferritic condition, with accompanying precipitation of carbide, if the holding temperature is within the range in which carbide exists as a separate phase. The progress of the transformation can be followed experimentally by methods that will not be discussed in detail here, since they have been described in the literature.[1,2,3] A graphic representation of the course of transformation is best obtained by plotting the percentage of austenite that has transformed, against the corresponding time that has elapsed at temperature, as illustrated in the upper portion of Fig. 1. The general form of this graph is typical of the course of transformation of a particular steel at constant temperature; the position of the curve on the time scale, and the slope depend both on the temperature level and on the actual composition and grain size of the austenite undergoing transformation.

For any one steel, most of the useful information given by a series of such graphs, each representing a different temperature level, can be summarized in a single diagram, as illustrated in the lower portion of Fig. 1, in which the symbol *A* represents untransformed austenite, *F* represents ferrite, and *C*, carbide. This type of chart, variously known as the isothermal transformation diagram,[3,4] S-curve,[1] or transformation-temperature-time (TTT) curve,[5,6] is a convenient means of showing the time required for austenite to begin and to finish transforming at any temperature level below its range of stability. Thus the diagram may be regarded as a kind of map or working drawing that enables one to visualize or anticipate approximately how the steel will behave and what structural changes will take place when it undergoes transformation from the austenitic state. The form and position of each of the curves constituting the diagram depend on the composition and grain size of the austenite that is undergoing transformation. Certain alloying elements or combinations of elements change the form of the curve in a characteristic way; a few typical examples, illustrating these alloying effects in terms of the isothermal transformation diagram, are presented in this article. With few exceptions, an increase in alloy content or in grain size of the austenite always *retards* transformation (moves the curves toward the right), at least at temperature levels higher than about 900 F—that is, at and above what is known as the "nose" or "knee" of the curve. This retardation is reflected in the greater hardenability of steels of higher alloy content or of coarser grain.

The significance and usefulness of the diagram in modern heat treating practice have been discussed at length

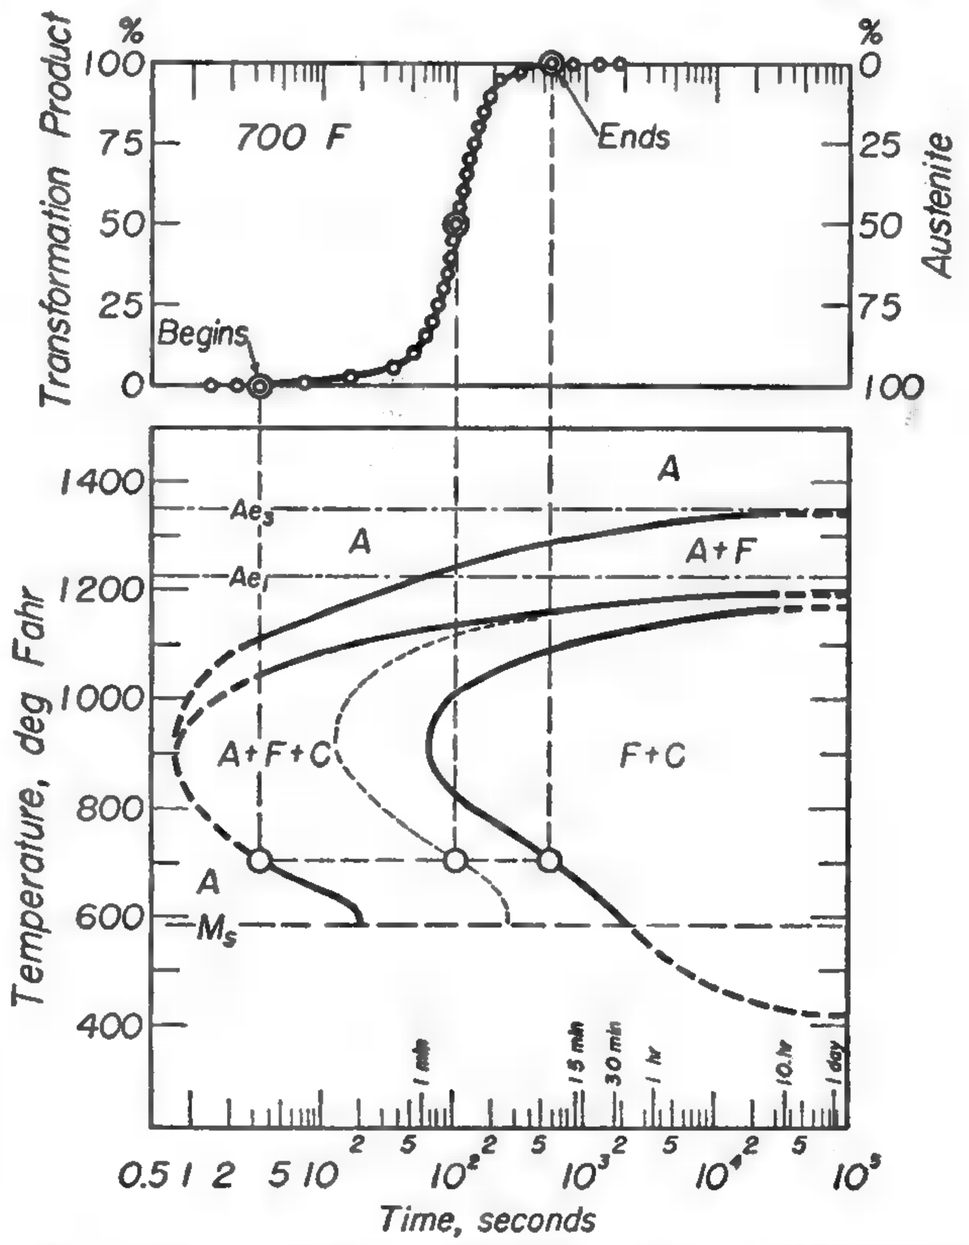

Fig. 1 Typical isothermal transformation curve at a single temperature, and its relation to the complete isothermal transformation diagram

elsewhere[1,3,4,6,7,8] and cannot be covered fully in this article. It must suffice to say that the isothermal transformation diagram is being used, on an ever widening scale, as the scientific basis of heat treatment; for it is

* Assistant to Vice President, United States Steel Corporation of Delaware, Pittsburgh

Prepared for the Subcommittee on Alloying Elements in Steel.

now generally recognized that the response of a steel to any specified heat treatment which involves the transformation of austenite is governed largely, if not entirely, by those factors which influence the time required for such transformation and the temperature at which it occurs; hence by the shape and position of the curves comprising the isothermal diagram. Perhaps the greatest usefulness of the diagram lies in the over-all picture that it presents of the transformation behavior of austenite. With this general concept in mind, it is possible to interpret and correlate many observed phenomena on a rational basis. Thus the metallurgist or heat treater can plan more intelligently the steps he must take to solve many of his problems.

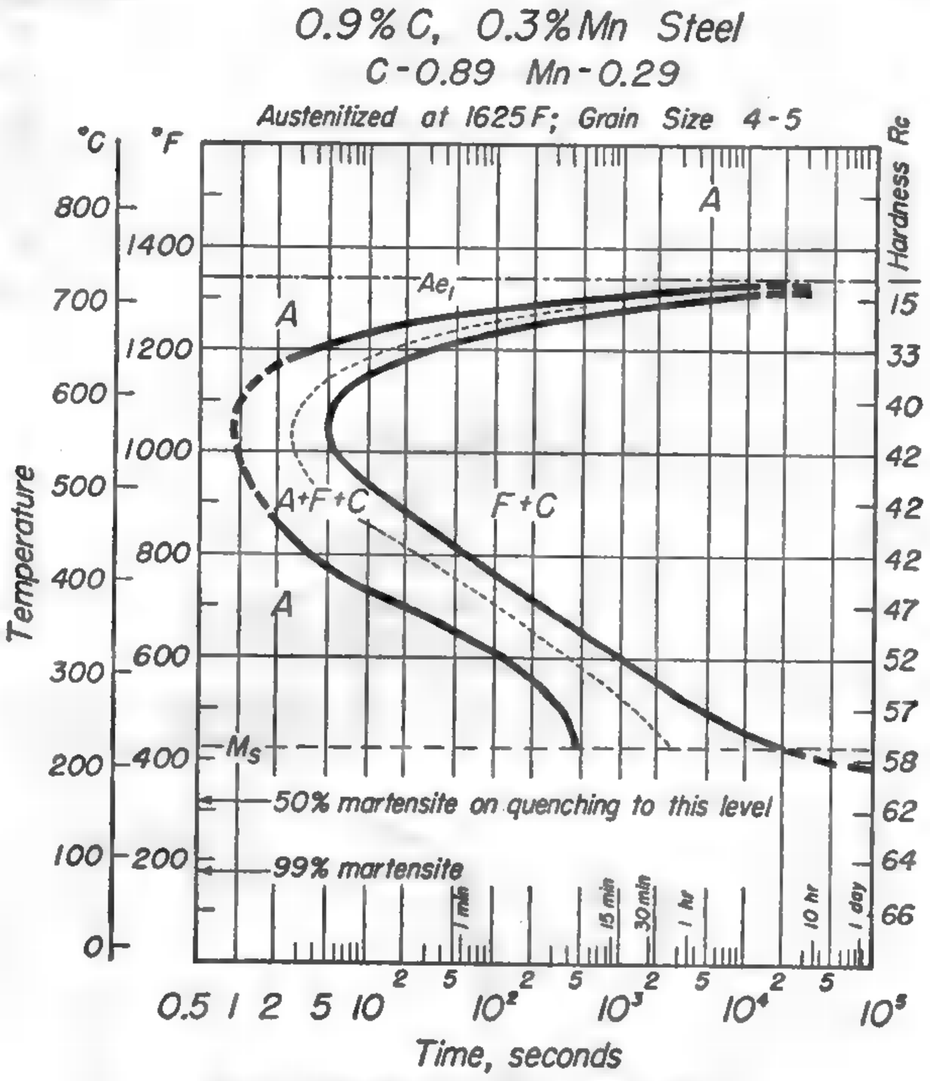

Fig. 2 SAE 1095, eutectoid carbon steel

Features Common to All the Diagrams. Before passing to a discussion of typical diagrams illustrating the effects of specific alloying elements in steel, it may be helpful to point out certain features more or less common to all the charts, and to discuss briefly the significance of the various lines and fields of the diagram. Figure 3 will serve to illustrate this discussion.

At the top of each chart there is sufficient information to identify the steel with respect to significant chemical composition, the austenitizing temperature employed and the grain size of the austenite developed at that temperature. In the left-hand margin appear the temperature scales; the basic scale is in degrees Fahrenheit. Time is plotted on a logarithmic scale along the horizontal axis; the basic scale at the bottom of the chart is in seconds, with a few representative time intervals shown in terms of minutes, hours or days, for convenience in locating quickly some familiar reference points on the time scale. In the right-hand margin is the Rockwell C hardness of the structure at room temperature, after substantially complete transformation at each different temperature level. At the bottom of this column is the full martensitic hardness achieved by quenching a small sample in brine, directly from the austenitizing temperature employed.

The Ae_1 and Ae_3 temperatures, shown as horizontal dot-dash lines at the appropriate temperature levels, are based on actual determinations under equilibrium conditions. When the lines of the diagram are considered in order, from left to right, the first heavy, curved line represents the time for beginning of transformation at any temperature level. In hypoeutectoid steels, this initial transformation consists of the separation of proeutectoid ferrite at temperatures between Ae_3 and the "knee" of the curve, which is in the range from 900 to 1100 F for most hypoeutectoid steels. The field above and to the left of this beginning line is marked *A* to indicate that in this time-temperature region the steel consists entirely of austenite *A*, which may be either stable or unstable, depending on whether it is above or below the Ae_3 temperature. At temperatures between the "knee" of the curve and the Ae_1 temperature, the initial separation of proeutectoid ferrite in hypoeutectoid steels is followed, without interruption, by simultaneous separation of both ferrite and carbide in the form of pearlite. The beginning of this pearlite reaction is represented by the second heavy curved line, and the field between these two uppermost curved lines is marked $A + F$ to indicate that austenite *A* and ferrite *F* exist simultaneously in this time-temperature region; the amount of ferrite increases with time at the expense of the austenite. Below the "knee", only a single beginning line is needed, since no proeutectoid constituent separates before bainite, which is the product of transformation at temperatures below the knee and down to "M_S", the highest temperature at which any martensite forms.

The right-hand curved line represents the time for completion of transformation at each temperature level, and the field between the left-hand and right-hand curves is labeled $A + F + C$ to indicate that austenite *A*, ferrite *F*, and carbide *C* all coexist in this time-temperature region; the ferrite and carbide increase in amount at the expense of the austenite as transformation proceeds to completion. The thin dotted line within the $A + F + C$ field represents the time required for half of the total transformation to take place at each temperature level. The field to the right of the right-hand curve is labeled $F + C$ to indicate that all the austenite has disappeared when this field is reached and that the final structure at completion of transformation consists only of ferrite and carbide.

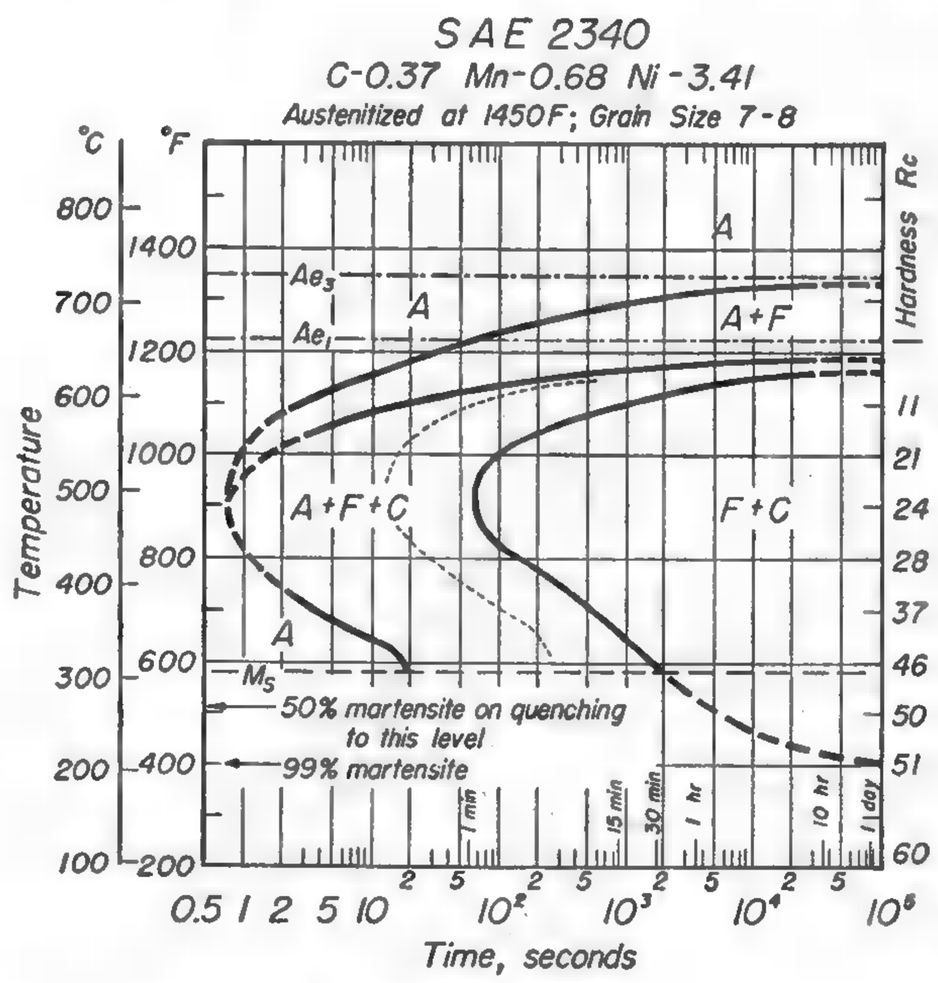

Fig. 3 SAE 2340, nickel steel

The lower portion of the diagram is arranged to indicate, by a horizontal dashed line, the location of the M_S temperature, which is the highest temperature at which any detectable amount of martensite forms on continuous cooling of austenite at rates faster than the critical cooling rate. Strictly speaking, such a datum has no place on a diagram that otherwise depicts only isothermal transformation, as contrasted with transformation during continuous cooling. It is included, nevertheless, because knowledge of the M_S temperature is useful in practical heat treating operations, and in the future most isothermal transformation diagrams will undoubtedly

include this information in some form. (*See* the articles on pages 263 and 611 in this Handbook.) In addition to the M_s temperature, the lower portion of the diagram shows the temperatures at which approximately 50% and 99% martensite are achieved on continuous cooling at rates faster than the critical cooling rate. The prolongation of the isothermal ending line, shown at the lower right of the charts as a heavy dashed curve, represents the probable time for completion of isothermal transformation of any austenite remaining after initial formation of martensite during cooling.

A typical diagram has been described above. Now a few actual examples will be discussed to show the influence of alloying elements on the isothermal transformation diagram. The diagrams selected, taken from a single publication,[4] have been modified to the extent of adding the M_s temperature and related data pertaining to the formation of martensite.

SAE 1095, Plain Carbon Steel of Eutectoid Composition. Figure 2 shows the isothermal transformation diagram for eutectoid carbon steel, which, because of the eutectoid composition of the steel and its consequent freedom from proeutectoid constituents, is the simplest of all the diagrams to be discussed in this article. It consists merely of the two principal curves, one for the beginning and the other for completion of transformation. Since the steel is of eutectoid composition, no proeutectoid ferrite is formed; hence there is no $A + F$ field in the diagram.

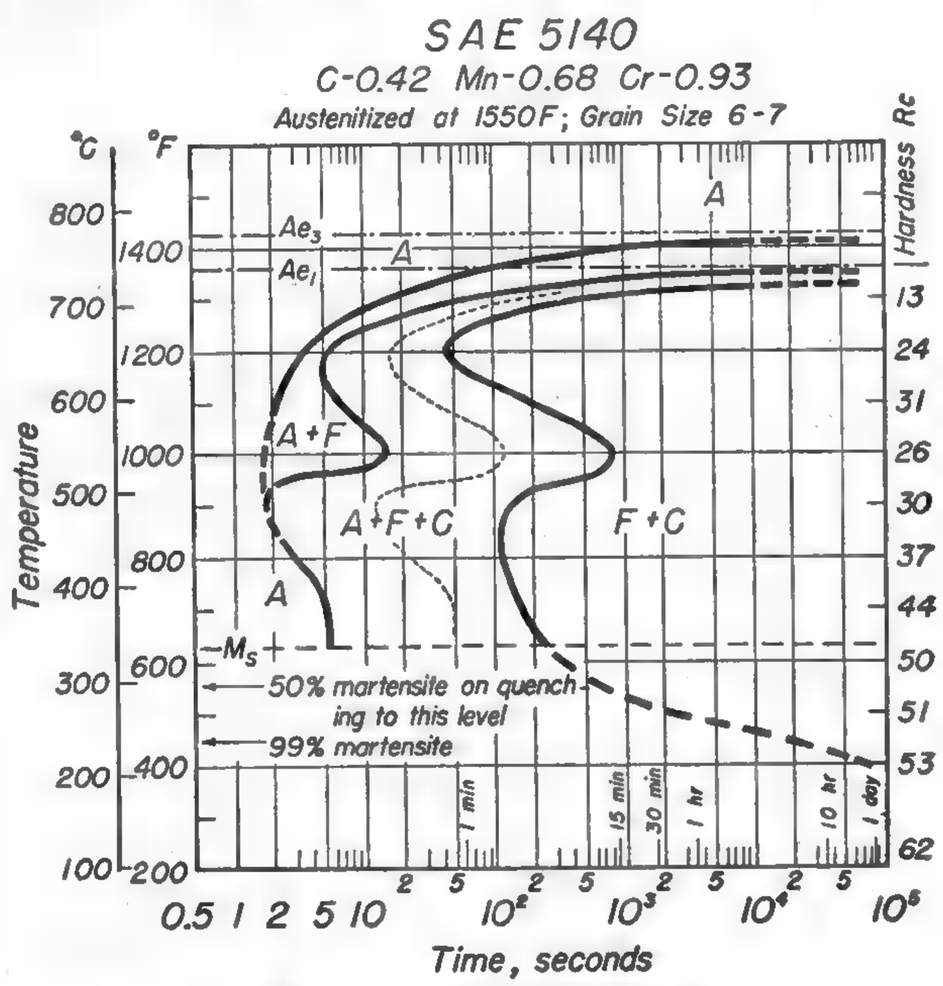

Fig. 4 SAE 5140, chromium steel

In diagrams for hypoeutectoid steels, an $A + F$ field appears above and to the left of the curve representing the beginning of pearlite formation, as shown in Fig. 3, 4, 5, 6 and 7a. On the other hand, in diagrams for hypereutectoid steel there is an $A + C$ field in ■ corresponding location, because proeutectoid carbide is the excess constituent rather than the ferrite which appears in hypoeutectoid steels; Fig. 7b is an example of such hypereutectoid behavior. Both hypoeutectoid and hypereutectoid carbon steels transform more rapidly than eutectoid steel in the vicinity of the knee of the curve (900 to 1100 F). This is particularly true for hypoeutectoid steels, and the lower the carbon content the more the beginning curve is moved toward the left of the diagram. The low hardenability of low-carbon steels is, of course, a direct reflection of this rapid transformation behavior. Increasing the carbon content depresses the M_s point and retards transformation appreciably at the lower temperature levels, as illustrated in Fig. 7a and 7b, to be discussed later; this effect of carbon content on M_s and on transformation rates at low temperature level shows no reversal when the carbon content exceeds that of the eutectoid.

SAE 2340, 3.5% Ni Steel. Figure 3 shows the isothermal transformation diagram for a typical hypoeutectoid alloy steel containing about 3.5% Ni and 0.4% C.

The hypoeutectoid nature of this steel is clearly indicated by the well-defined $A + F$ field. Note the rather low Ae_1 and Ae_3 temperatures resulting from the nickel content. Comparison of this diagram with Fig. 2 serves to emphasize the considerable increase in sluggishness of transformation contributed by the addition of nickel and manganese, as shown by the greater spread between beginning and end of transformation, particularly in the temperature range from 1100 to 600 F. It should be noted also that the higher M_s temperature of the SAE 2340 steel is caused by its lower carbon content and not by the alloying elements present in the steel.

In general, this diagram for SAE 2340 is simple in form and may be considered the hypoeutectoid counterpart of the eutectoid steel shown in Fig. 2, allowing for the special features contributed by nickel and manganese, as discussed above.

SAE 5140, 0.9% Cr Steel. Figure 4 is the isothermal transformation diagram for another typical hypoeutectoid alloy steel, in which chromium is the principal alloying element.

The relatively small size of the $A + F$ field should be noted; also the small gap between Ae_1 and Ae_3, as compared with SAE 2340 (Fig. 3). These features indicate that SAE 5140 is much closer to eutectoid composition than SAE 2340. Note also the peculiar form of the lines that represent the beginning and ending of transformation to the $F + C$ aggregate structures in the vicinity of 1000 F. These features are characteristic of diagrams for chromium steel and are accentuated in alloys that have a higher percentage of chromium. In fact, most of the alloying elements that are classed as strong "carbide formers" tend to introduce similar retarding effects in the beginning and ending of transformation at temperatures in the range from 1200 to 900 F. Attention is again directed to the relative sluggishness of transformation, once it is started, in this alloy steel as compared with eutectoid carbon steel (Fig. 2).

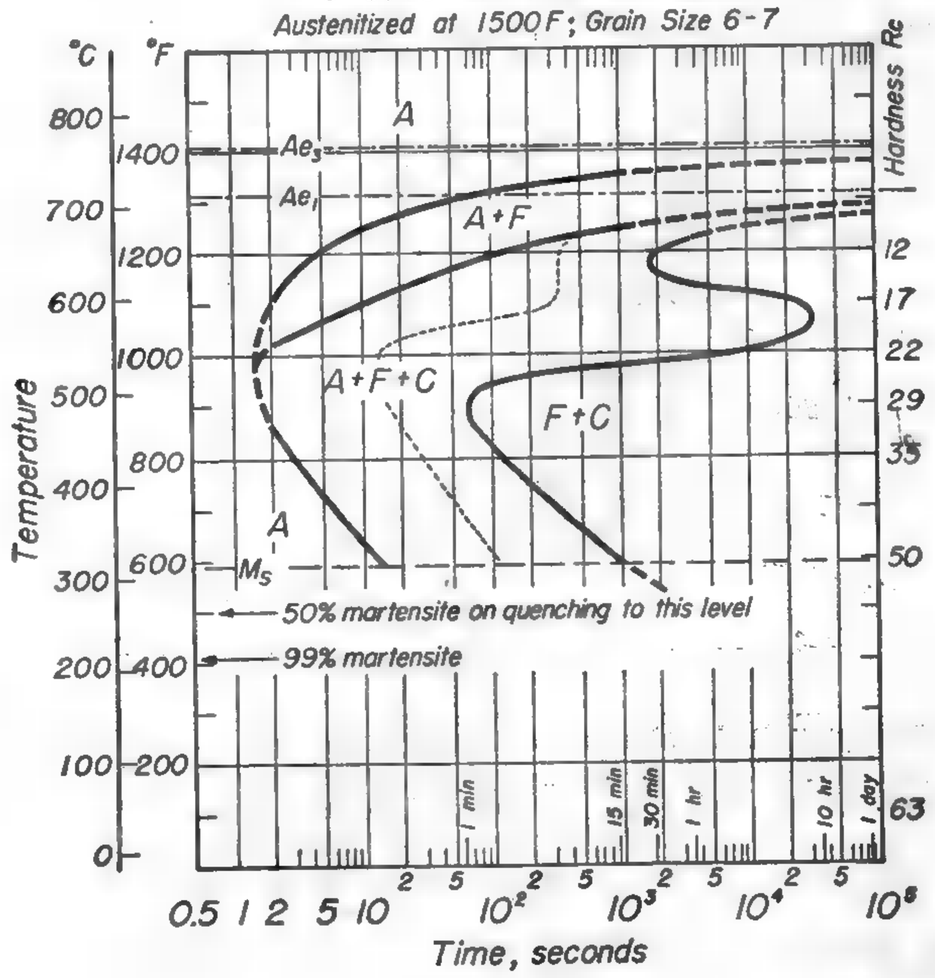

Fig. 5 SAE 4047, molybdenum steel

The effect of chromium, as discussed above, is to slow down transformation and hence contribute to increased hardenability.

SAE 4047, 0.5% C–0.25% Mo Steel. The isothermal transformation diagram for this steel (Fig. 5) serves to illustrate the powerful influence of a small amount of molybdenum in retarding transformation, particularly at temperatures above approximately 900 F.

This steel is distinctly hypoeutectoid, as indicated by the well-defined $A + F$ field. The marked protuberance in the ending line, at about 1050 F, is rather characteristic of diagrams for molybdenum steel and is accentuated by higher percentages of molybdenum; however, this retarding effect does not seem to increase proportionally when the molybdenum content is more than about 0.5%.

SAE 4340, Nickel-Chromium-Molybdenum Steel. Figure 6 illustrates the isothermal transformation diagram of this deep-hardening, triple-alloy steel and constitutes a striking example of the influence of this particular combination of alloying elements in changing the shape and location of the curve.

In spite of the relatively high alloy content, this steel exhibits hypoeutectoid characteristics as evidenced by the $A + F$ field, which in this diagram extends to about 1100 F, beneath the pearlite knee, in contrast with the $A + F$ field in diagrams discussed previously. It should be noted that this diagram has two knees in the beginning line, as does SAE 5140 (Fig. 4)—an upper one at approximately 1150 to 1200 F, and a lower one at approximately 850 F. The upper or "pearlite knee" is pushed quite far to the right on the time axis by the high alloy content, while the lower or "bainite knee" juts out to the left below the 950 F "shelf". It is characteristic of such steels that, at temperatures just below the shelf, the isothermal transformation more nearly approaches completion the lower the temperature.

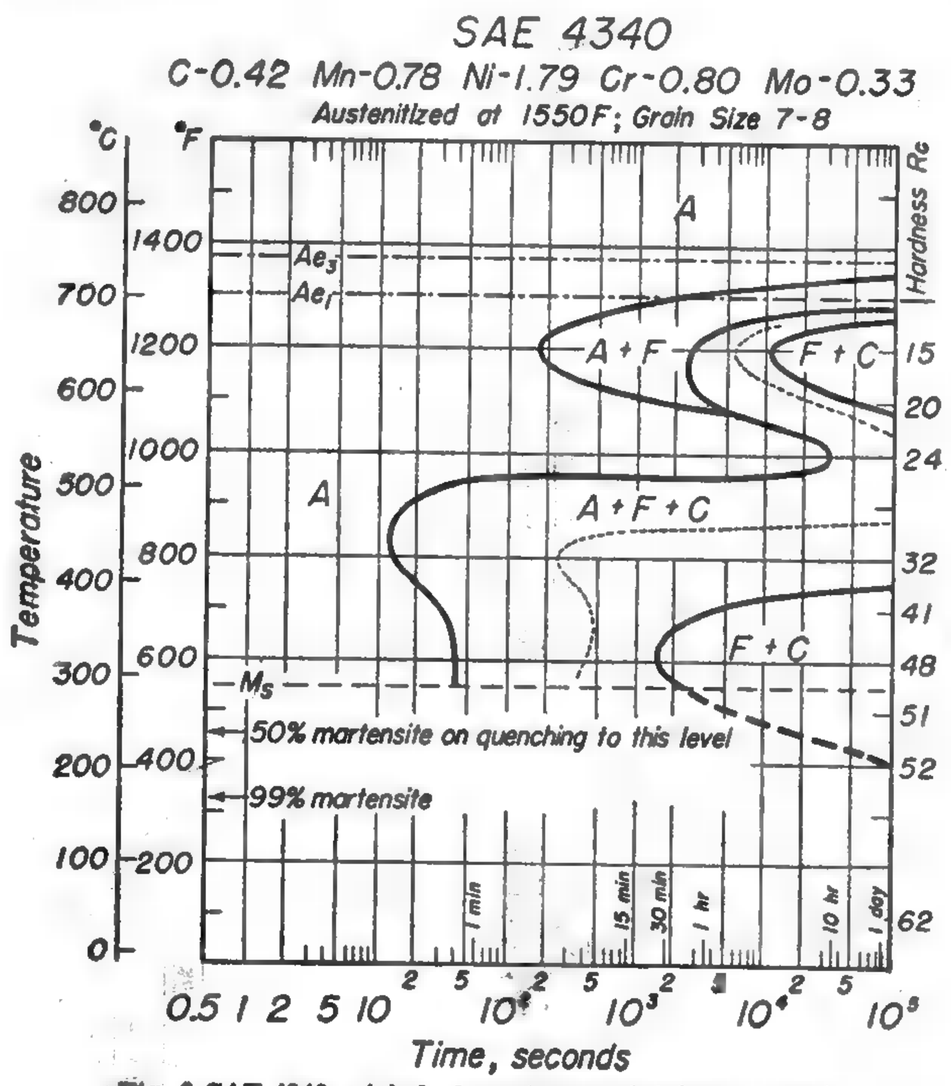

Fig. 6 SAE 4340, nickel-chromium-molybdenum steel

In quench hardening a steel that has an isothermal transformation diagram of this general type, it is the lower knee that is of primary interest, rather than the upper one, since the cooling curve must fall essentially to the left of this lower knee if full hardening to martensite is to be achieved. A substantial number of steels have an isothermal transformation diagram of this general type.[7] In such steels the vicinity of the lower knee, in the range from 800 to 950 F, is where transformation starts rather promptly but is extremely sluggish in going to completion. The reaction in this range exhibits certain complexities in the form of multiple-stage transformation of the austenite; these complex reactions have been discussed in some detail elsewhere.[3] The structures which form in this temperature range in some steels may have mechanical properties less desirable for certain applications than a fully hardened and tempered martensitic structure.

SAE 4815, Nickel-Molybdenum Steel, Uncarburized and Carburized. Figures 7a and 7b show the isothermal transformation diagrams of a typical alloy carburizing steel in the uncarburized and carburized condition, respectively. The diagrams illustrate the effect of low and high carbon content on the shape and characteristics of the curves, when all other variables are essentially constant.

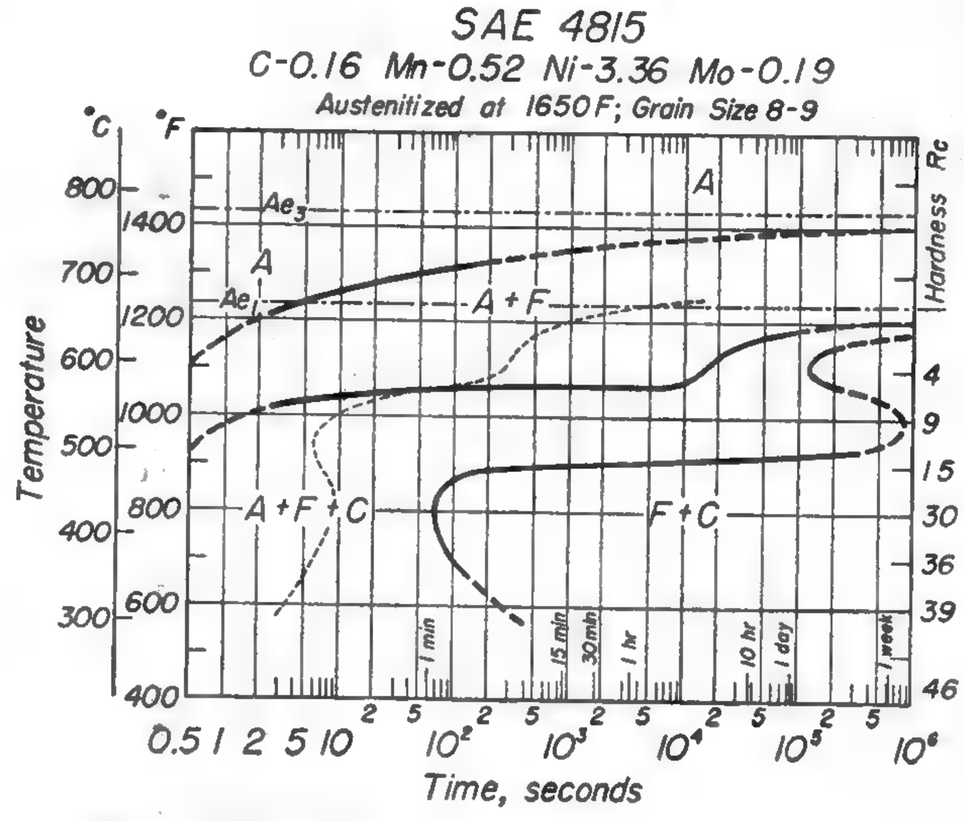

Fig. 7a SAE 4815, nickel-molybdenum steel, uncarburized

The diagram for the uncarburized material (Fig. 7a) exhibits the characteristic features of a distinctly hypoeutectoid steel; namely, a pronounced $A + F$ field and very rapid onset of transformation at temperatures in the vicinity of the knee and below. Note the lowering of the Ae_1, resulting from the relatively high nickel content; note also the marked protuberance in the ending line, characteristic of steels containing molybdenum.

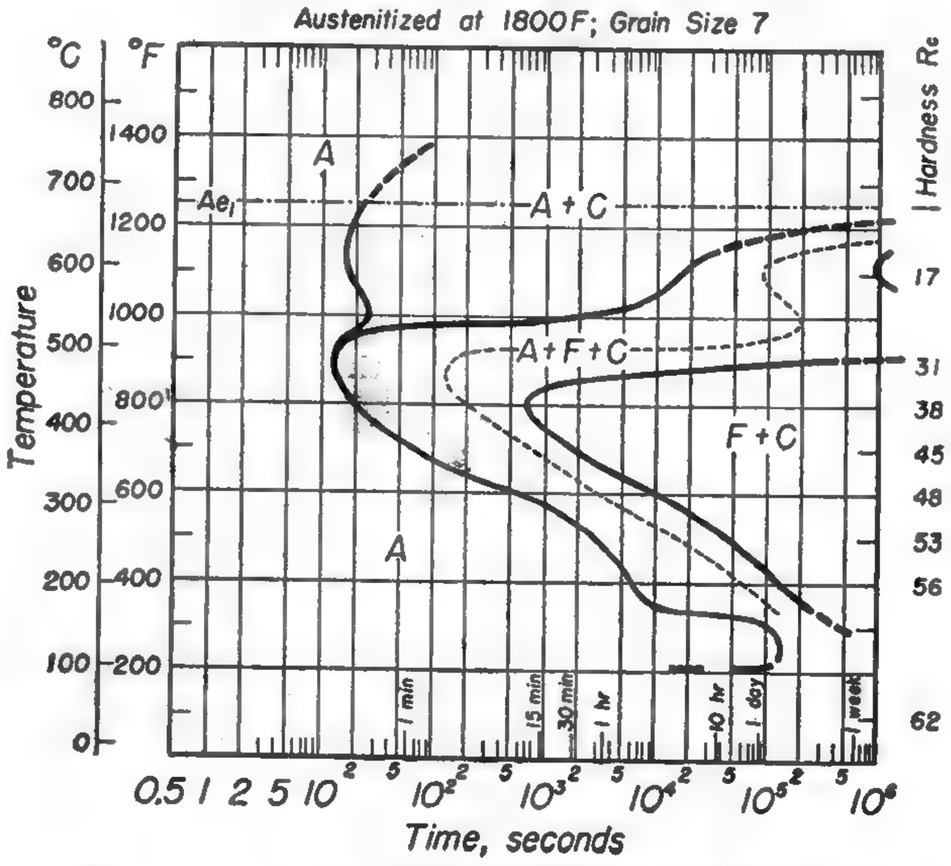

Fig. 7b SAE "48100", nickel-molybdenum steel, carburized

In contrast, the diagram for the carburized material (Fig. 7b) is distinctly different in almost every feature. In the first place, the steel necessarily exhibits hypereu-

tectoid behavior, as evidenced by an $A + C$ instead of an $A + F$ field. The increase in carbon content has retarded both the beginning and ending of transformation at all temperature levels; this is particularly evident at 1000 F and below. Note also the marked lowering of the M_s temperature as a result of the high carbon content. As a matter of fact, the M_s temperature could not be measured reliably for the uncarburized material, because of its low carbon content and consequent rapid transformation, but a calculated value based on chemical composition indicates that it would be about 730 F, in comparison with an M_s temperature of about 205 F for carburized material.

Summary. The typical diagrams discussed above should give a fairly comprehensive picture of the effects of alloying elements as revealed by studies of isothermal transformation. Some variation in details of diagrams may be expected, depending on the particular combinations and amounts of alloying elements present in the steel,[7] but most of the diagrams that have been determined to date will correspond approximately to one or another of the types illustrated and discussed in this article. It should also be borne in mind that significant variation may occur in some details of the diagram for a nominal grade of steel, depending on whether the composition is on the high or low side of the specification range.

The Temperature Range of Martensite Formation in Steel

By P. Payson* and R. A. Grange*

THE FIRST to study the temperature range of the austenite-to-martensite transformation in carbon steels were apparently Portevin and Garvin[1] in 1919. A short time later, Matsushita[2] observed that continuous formation of martensite requires continuous cooling, and that if cooling is interrupted, the formation of martensite stops; if cooling is resumed, more martensite is formed. Based on an investigation by Hanemann and Wiester,[3] a movie film was prepared that showed martensite needles forming from austenite in a 1.65% C steel; the time required for each needle to form was less than 0.05 sec. These classic investigations, together with many of more recent date, show that martensite forms when austenite in any given steel is cooled below a certain temperature, now generally designated "M_s". Each martensite needle forms almost instantaneously. The proportion of martensite depends on the temperature finally reached during cooling. The temperature at which virtually all the austenite has transformed to martensite is called "M_f".† Between M_s and M_f, the proportion of martensite is greater the lower the temperature reached during cooling; thus, martensite forms only during cooling and not during a time period that is measurable by any ordinary method, at constant temperature. For further discussion concerning the characteristics of the martensite transformation, the reader may refer to the article on page 263 in this Handbook.

Table I. Influence of Alloying Elements on the M_s Temperature of Steel

Alloying Element	References	Qualitative Effect
Carbon	4, 5, 6, 7, 8, 9, 10, 11, 12, 13	Lowers M_s strongly
Manganese	13, 14, 15, 16, 17, 18, 19, 20	Lowers M_s
Silicon	16, 19, 21	Almost no effect
Nickel	13, 16, 19, 20, 21	Lowers M_s
Chromium	13, 16, 19, 20, 22, 23, 24, 33	Lowers M_s
Molybdenum	16, 19, 20, 21, 25	(?) (a)
Vanadium	16, 26	Lowers M_s
Tungsten	16, 19	Lowers M_s
Copper	16, 19	Lowers M_s
Aluminum	16, 19	Raises M_s
Cobalt	16, 19, 21	Raises M_s

(a) Some investigators[21, 25] report that molybdenum has no effect on M_s; others [16, 19, 20] report a lowering.

The M_s and M_f temperatures depend on the chemical composition of austenite, but not on over-all steel composition in instances where an appreciable percentage of any element remains undissolved in austenite. The grain size of austenite does not appear to be a significant factor, but segregation (banding) may have some influence since, locally at least, it affects the composition of austenite.

Effect of Composition. In recent years a number of technical publications have dealt specifically with the effect of composition on the temperature range of martensite formation. Such experimental measurements have been greatly facilitated by a metallographic technique first described by Greninger and Troiano.[4] Table I lists the qualitative effects of the various elements as determined by the investigators named in the references.

The several investigations have rarely been in good agreement as to the quantitative effect of a particular element on M_s, and a survey of the literature indicates the need for more experimental measurements; for this reason, a rather complete list of references has been given. Despite such limitations in the data available at present, empirical formulas given below have been proposed for calculating M_s on the basis of chemical composition; these have been found useful for estimating M_s in carbon and low-alloy steels. The M_s thus calculated and the measured M_s agree well enough for many practical purposes.

(1*) M_s (°F) $= 930 - 570 \times \%C - 60 \times \%Mn - 50 \times \%Cr - 30 \times \%Ni - 20 \times \%Si - 20 \times \%Mo - 20 \times \%W$ (reference 19)

(2*) M_s (°F) $= 1000 - 650 \times \%C - 70 \times \%Mn - 35 \times \%Ni - 70 \times \%Cr - 50 \times \%Mo$ (reference 20)

(3) M_s (°F) $= 925 \times (1 - 0.620 \times \%C) \times (1 - 0.092 \times \%Mn) \times (1 - 0.033 \times \%Si) \times (1 - 0.045 \times \%Ni) \times (1 - 0.070 \times \%Cr) \times (1 - 0.029 \times \%Mo) \times (1 - 0.018 \times \%W) \times (1 + 0.120 \times \%Co)$ (reference 27)

(4†) M_s (°F) $= 930 - 540 \times \%C - 60 \times \%Mn - 40 \times \%Cr - 30 \times \%Ni - 20 \times \%Si - 20 \times \%Mo$ (reference 34)

Any one of these formulas may be used to calculate the approximate M_s temperature of any *carbon* or *low-alloy* steel subject to the following limitations:

1 Essentially all carbides (therefore carbon and alloying elements) must be dissolved in austenite.
2 The carbon content must not be greater than about 0.85%; it is not known at present whether the formulas are applicable to steels of very low carbon content. In the development of the formulas only steels containing more than about 0.2% C were considered.

* Crucible Steel Company of America, Harrison, N. J.
* United States Steel Corp., Research Laboratory, Kearny, N. J.
Prepared for the Subcommittee on Alloying Elements in Steel
† There is some evidence that small amounts of austenite may be retained in almost any steel, even if quenched considerably below M_f, as ordinarily determined experimentally.

* Rowland and Lyle[32] suggest $-600 \times \%C$ instead of $-570 \times \%C$ for the carbon factor in this formula.
* Limited to steel containing less than 1.5% Cr and 1% Mo.
† Formula 4 is more accurate than Formula 1.

Very little work has been done concerning the effect of composition on the M_f temperature; what data are available[19,20] indicate that elements which lower M_s probably have an even greater lowering effect on M_f, thus widening the temperature range of martensite formation.

Significance and Usefulness of Data Concerning Martensite Reactions. A knowledge of the M_s temperature and of the progress of the martensite reaction with decreasing temperature, is important in the heat treatment and welding of steels, and may also be used for measuring depth of carburization, or of decarburization, in steels. In the ordinary hardening operation—that is, in the quenching and tempering procedure—it is desirable to know not only the M_s temperature but also the temperature at which the austenite-to-martensite reaction is virtually complete, so that the steel may be cooled sufficiently in the quench, or subsequent to the quench, before it is tempered. The M_s temperature establishes the temperature of the hot quench in the martempering treatment. For alloy steels of high hardenability, the M_s temperature determines the correct preheating temperature to be used when the steels are to be welded.[35] Finally, it is possible, by means of correlation between carbon content and the M_s temperature, to measure not only the extent of carburization or decarburization, but also the depth at which a particular carbon content exists.

As stated above, when steel is quenched from the austenitizing temperature at a sufficiently rapid rate to avoid transformation at higher temperatures, the austenite will begin to transform to martensite when it has cooled below the M_s temperature, and will continue to transform to martensite until it has cooled to the M_f temperature, at which virtually all the austenite will be transformed. If the cooling is stopped at any temperature above the M_f temperature, some austenite will remain that will not transform completely to martensite until the steel has eventually cooled to the M_f temperature or below. If, before being cooled to the M_f temperature, the steel is heated to the tempering temperature, and the tempering is done at a temperature at which the residual austenite does not transform isothermally during the time used, as would be true of many alloy tool steels,[28] the resulting structure will be a mixture of tempered martensite and austenite, and this austenite may finally transform to martensite when the steel is cooled to room temperature after the tempering operation. This final formation of martensite after tempering, may set up sufficient stress to crack the steel. At best, it will leave the steel with a mixture of tempered and untempered martensite, and retempering will usually be required in order to relieve the residual stresses.[28] In the higher-carbon alloy steels, such as high speed steel and the high-chromium die steels, the cessation of cooling in the original quench before the M_f temperature has been reached, causes the remaining austenite to become "stabilized" so that it will not transform in the usual manner when the steel is eventually cooled to room temperature or below. This "stabilized" austenite may require special treatments, such as conditioning tempering, or refrigeration at very low temperature, to cause it to transform to martensite.[29]

Inadequate cooling, which fails to permit nearly complete formation of martensite before the steel is tempered, is likely to cause distortion or cracking, particularly in large quenched sections. In these sections, the outside may be cooled to the M_f temperature at a time when the inside is at a temperature where the transformation to martensite may be, for example, only 50% complete. If the piece is tempered before further cooling takes place, the outside will be tempered martensite, but the inside, when the steel has cooled to room temperature after the tempering treatment, will be a mixture of 50% tempered and 50% untempered martensite or, if austenite transformed during the tempering, of up to 50% isothermal product.

The martempering procedure consists in quenching the steel into a bath at just above the M_s temperature, to avoid transformation at higher temperatures, and then allowing the steel to cool to room temperature in air. This permits the steel to transform gradually to martensite, and possibly to bainite, during the slow cooling in air, and allows the steel to accommodate itself, without cracking,[30] to the volume change that accompanies the transformation.

When medium-carbon and high-carbon steels are welded, the zone adjacent to the weld reaches a high temperature and then, if no precautions are taken, cools rapidly and transforms to martensite. This frequently causes cracks next to the weld bead. To prevent such cracking, the stock is usually heated just before the welding operation, and then is reheated immediately afterward. (These operations are referred to as "preheating" and "postheating".) The purpose of preheating is to prevent the formation of much martensite in the stock that is being welded. The purpose of postheating is to temper any martensite that may have formed and to permit the residual austenite to transform to the relatively soft products that are formed at the higher temperatures.

In the past, the selection of the preheating temperature has been more or less by rule of thumb. However, if the steel is preheated at, or close to, the M_s temperature and then is postheated at a high temperature at which the austenite will transform in a relatively short time, there can be no formation of martensite subsequent to the welding operation, and consequently there is complete assurance of freedom from cracking because of martensite formation, even in high-carbon steels of high hardenability.[35]

Since the M_s temperature is affected appreciably by the carbon content of the steel, it is possible, by following the quench-temper procedure of Greninger and Troiano,[4] to establish the carbon content at a given position in decarburized or carburized zones of a piece of steel. After the steel has been completely austenitized, if it is quenched into a bath known to be at the M_s temperature corresponding to a given carbon content, and is then tempered immediately, the portion that is lower in carbon content than the given value, will contain tempered martensite needles, and the portion that is higher in carbon content will be free from tempered martensite. The difference between the tempered and untempered martensite can be recognized readily in the etched microsections, and therefore demarcation between zones of different carbon content can be recognized quite easily by use of the data concerning martensite reactions.[19,31,32]

Principles of Heat Treatment of Iron and Steel

By E. S. Davenport*

THE purpose of this article is to outline the principles underlying the heat treatment of ferrous materials. These fundamental principles are used when the mechanical properties of steel are intentionally altered by heat treatment in order to make the steel more serviceable for some particular purpose.

An article on the subject of heat treatment of metals in general appears on page 255. The present article is confined to the heat treatment of steel and, moreover, is limited to a discussion of principles. The closely related subject of isothermal transformation of steel (S-curves) is discussed in an article on page 607.

In general, all heat treating processes involve two fundamental operations: heating and cooling. A third factor — the element of time at one or more temperatures, either in the heating or the cooling step — must be taken into consideration in making a schedule for heat treatment of any particular steel. Some of the questions that must be answered in developing such a schedule are: How hot and at what rate should the steel be heated? How long should it be held at temperature? At what rate should it be cooled? Is the heat treatment to be considered finished at the end of the cooling step or is a tempering treatment required? If tempering is necessary, what heating, cooling and time-temperature procedures are to be followed? In the following paragraphs these questions are considered in some detail, and an attempt is made to base answers on general principles.

Heating. The first step in the heat treatment of steel is the heating of the material to some temperature either in or above the transformation range, to put the iron in the gamma condition; carbon and other elements are thus dissolved in the gamma iron, forming the solid solution, austenite. The solution of these elements may be either partial or complete, depending on the time-temperature cycle. This austenite solid solution is the raw material from which is built the final structure of ferrite and carbide in the subsequent cooling and tempering.

Rate of Heating. For many purposes the rate of heating is less important than certain other essential factors of the heat treating cycle; for example, maximum temperature, time at temperature, and rate of cooling. The initial condition of the material, with respect to residual stress produced by cold work or otherwise, may have an important bearing both on the optimum rate of heating, because of the influence of this rate on distortion and cracking, and on the initial size and growth characteristics of the austenite grains; moreover, in the selection of a heating rate, it is necessary to consider the volume change accompanying the alpha-to-gamma transformation as the metal passes through the transformation range. Hard, brittle, highly stressed materials, such as steels in the martensitic or fully hardened condition, should be heated more slowly and carefully than stress-free materials; otherwise cracking may occur. However, materials that have been subjected to a certain amount of cold working may exhibit a tendency toward germinative or excessive grain growth when heated slowly through the transformation or recrystallization range; such materials require rather rapid heating through the germinative temperature range to avoid excessive grain growth.

The thermal conductivity of the material, the nature of the furnace atmosphere (scaling or nonscaling) and the thickness of section, all influence the behavior of the steel in relation to the rate of heating. The difference in temperature rise within thick and thin sections of articles of variable cross section is a problem always present in practical heat treating operations; whenever possible, provision should be made for retarding the heating of the thinner sections in order to minimize thermal stress and distortion. Uniformity of proper temperature throughout the material is the ultimate objective of the heating cycle; usually this uniformity will be attained more safely by slow heating than by rapid heating, and with less over-all damage to the steel.

Maximum Temperature. The selection of the maximum temperature will be determined partly by the chemical composition of the steel, the proportion of carbide or ferrite desired in solution in the austenite, and the maximum permissible size of austenite grains if the grain size has been defined or specified. In general, the higher the temperature, within limits, the greater the solubility of the phases (carbide or ferrite) and the greater the rate at which they are dissolved in the austenite; likewise, the higher the temperature, the larger the austenitic grain size, if other factors are equal.

For plain carbon hypoeutectoid steels (carbon content less than about 0.8%) a temperature just *above* the upper transformation or critical temperature (A_3) is usually recommended. At this temperature (A_3), which varies with the carbon content of the steel, the transformation from alpha to gamma during heating is just completed; that is, all the carbide and proeutectoid ferrite is in solid solution; thus maximum solubility of the constituents is achieved with minimum growth of the austenite grains. As the temperature is raised above the A_3 for any given steel, the austenite grains begin to grow. Such grain coarsening is sometimes desirable for improving machinability; less frequently grain coarsening is employed to increase hardenability (depth of hardening) although deeper hardening can usually be achieved better by other means.

For plain carbon hypereutectoid steels (carbon content more than about 0.8%) a recommended temperature is usually *between* the lower transformation or critical temperature (A_1) and the upper transformation (A_{cm}). The upper transformation line (A_{cm}) in the iron-carbon diagram rises so steeply when the carbon content is increased to more than 0.85% that an excessively high temperature may be required for dissolving all the proeutectoid carbide in the austenite; this tends to develop undesirably coarse austenitic grain size with consequent deep hardening and cracking. If it is desirable to take full advantage of the hardening effect of the carbon and of the alloy content, it may be necessary to have most of the carbide in solution, a condition that requires a temperature just at, or slightly above, the A_{cm} temperature; otherwise, it may be preferable to leave some of the carbides undissolved, in order to restrain austenitic grain growth and to act as transformation nuclei during cooling. When this is done, part of the potential hardenability of the steel is sacrificed in order to limit or control grain growth and depth of hardening. Undissolved carbides are almost always present in the austenite of alloy steels that contain the reluctantly soluble carbides of elements such as chromium, vanadium, molybdenum and tungsten; excessively high temperature or an absurdly long heating period would be required to put all these carbides into solution.

To summarize, the maximum temperature in the austenitic range should be just high enough to achieve the necessary extent of solution of the ferrite or carbide.

Time at Maximum Temperature. In general, time at temperature has an influence similar to maximum temperature, as discussed in the preceding section. In any heat treating process, *temperature* and *time* must be considered simultaneously since virtually all changes in metals take place more rapidly at higher temperatures, as a result of increased atomic mobility. Thus the longer the time at any given temperature in the austenitic range, the greater will be the amount of carbide and alloying elements (if present) taken into solution; the more homogeneous the austenite because of diffusion of these dissolving elements; and the larger the austenitic grain size—all within limits fixed by the equilibrium conditions of these reactions at the specific temperature under consideration. Carbide par-

ticles, in particular, require a surprisingly long interval of time for complete solution, even when the temperature is such as to cause their ultimate solution, that is, above A_{cm}.

Since the constitutional changes that may be brought about at the maximum temperature are comparatively rapid, the element of time is less important than the actual temperature. In general, a relatively small increase in temperature will have a far greater effect in accomplishing the desired change than a longer time at a lower temperature; this is true in the diffusion and grain-growth changes mentioned above. However, the factor of time appears more significant when the question of time at temperature is considered from the standpoint of thickness of section, thermal conductivity of the metal, scaling, decarburization and other surface reactions that depend on furnace atmosphere. The heavier the section or the lower the thermal conductivity, the longer the time necessary to attain uniform temperature throughout the piece; and in the heat treatment of most parts, uniformity of temperature throughout the part is highly essential. Scaling, decarburization and similar surface phenomena all proceed continuously with time at temperature; if these effects prove detrimental, the heat treater had best keep the time as short as possible. Many of these surface reactions can be limited or even advantageously utilized by proper adjustment of the furnace atmosphere as, for example, when elements are introduced intentionally into steel by carburizing, nitriding or a similar treatment.

Ordinarily the time at maximum temperature should be long enough to attain uniformity of temperature and to bring about the desired constitutional changes. Frequently these two aims require approximately the same time.

Cooling. When the steel has attained the predetermined temperature throughout, the next step is to cool it at the proper rate to develop the desired structure. When, during the cooling of a given steel, the austenite transforms to an aggregate of ferrite and carbide or to martensite, the resultant structure—hence the mechanical properties—is determined largely by the temperature at which this transformation actually takes place. With a slow rate of cooling only moderate undercooling occurs; the transformation takes place at a temperature slightly lower than the lower transformation temperature (A_1), and the resulting structure is characterized by coarse lamellar pearlite of relatively low strength and hardness and high ductility. In addition to the pearlite reaction, when cooling is slow, there is a precipitation of proeutectoid ferrite in hypoeutectoid, or carbide in hypereutectoid steels; these proeutectoid constituents usually precipitate in the austenite grain boundaries and thus outline the austenite grains that existed at the maximum temperature; advantage is taken of this behavior when the grain size of austenite is measured in hypoeutectoid and hypereutectoid steels.

With progressively higher rates of cooling, the actual temperature of transformation is progressively lowered by undercooling, until eventually it is depressed to temperatures in the vicinity of 950 to 1000 F; the lamellar pearlite becomes progressively finer, stronger, harder and less ductile, and the precipitation of the proeutectoid phases—ferrite or carbide—gradually diminishes in volume until finally, at the faster cooling rates, this precipitation may be suppressed altogether. However, in the very low carbon steels (0.20% and lower) so much excess ferrite is available that precipitation cannot be suppressed ordinarily, even with the most drastic cooling.

If the speed of cooling is increased still further, as in quenching, the transformation is depressed by undercooling to temperatures approaching room temperature; the product of the austenite transformation at these low temperatures is not pearlite, but martensite, the characteristic constituent of fully hardened steel. The cooling rate that just causes the steel to harden fully to the martensitic condition is known as the "critical cooling speed"; it depends on the composition and the austenitic grain size of the steel. Martensite is now generally considered to be an unstable, supersaturated solid solution of carbon in alpha iron; it is glass-hard, brittle and, in steels carrying more than about 0.5% C, always in a condition of high stress, caused in part by the volume changes accompanying the gamma-to-alpha transformation, by the solid-solution effect, and by the drastic cooling which the material underwent in the hardening operation. In this condition, steel is ready to precipitate the carbon that it contains and to be relieved of stresses at the first opportunity; for example, on reheating for tempering. Under some circumstances, fully hardened steel may be relieved of stresses by spontaneous cracking, a fact well known to practical heat treaters.

At cooling rates intermediate between those that give rise to the pearlitic structures and those that yield martensite, mixtures of the two structures may be formed, since part of the transformation occurs at the higher temperatures and part at the lower; this mixed structure is always encountered in the transition zone between the hardened exterior and unhardened core of quenched heavy sections in which the surface may have cooled fast enough to form martensite, while the interior cooled more slowly and transformed to the softer pearlitic products at higher temperature. Thus it is evident that thickness of section has a great influence on the depth to which a given steel may harden under any specific cooling conditions.

Effect of Alloying Elements. The mechanism is now fairly well understood by which, at any particular cooling rate, dissolved alloy content depresses the transformation to lower temperatures, as compared with carbon steel. The alloying elements generally retard the transformation rate of the austenite, causing the finer, harder pearlitic structures to be formed at any given slow rate of cooling, or causing deeper hardening characteristics during rapid cooling—all as compared with plain carbon steels. The net effect corresponds to a faster cooling rate before the beginning of transformation, as compared with carbon steel. A so-called "air-hardening" steel, therefore, is one in which the transformation rate has been so retarded by the addition of alloying elements as to form fully hard martensite, even on moderately slow cooling from the austenitic condition. In high-alloy steels that contain substantial amounts of the elements that stabilize austenite, the austenite solid solution may be retained all the way to room temperature by the use of very moderate cooling rates, such as air cooling. These steels constitute extreme examples of the retarding of the transformation rate by the addition of alloying elements.

Effect of Austenitic Grain Size. Increasing the grain size of the austenite by employing higher maximum temperatures before cooling, has an effect on hardenability similar to that of adding alloying elements; coarsening the austenitic grain retards the transformation rate and results in harder, finer pearlitic structures or in deeper hardening characteristics for any given rate of cooling, as compared with the same steel in the fine-grained condition.

Effect of Thickness of Section. The influence of size of section must be taken into account in any consideration of heat treatment from the standpoint of cooling rate. A heavy section cannot be cooled as rapidly as a thin section; the interior of a heavy section, cooling more slowly than the surface, transforms not only at a later time but also at a higher temperature, and hence to a softer product than the exterior, which cools more rapidly. This gives rise to differences in properties between the interior and exterior, as well as to possible distortion, nonuniform stress and other difficulties well known to those familiar with heat treating practice; the subject is discussed more fully on pages 629 and 636 in this Handbook.

Effect of Surface Condition. Another factor involved in cooling practices is the surface condition of the metal about to be cooled. Steel that carries a heavy insulating coating of scale from the heating operation cannot be cooled as rapidly, under a given set of cooling conditions, as steel free from scale. This may result in erratic and nonuniform properties in the final product, particularly in connection with treatments designed to achieve full hardening. Soft spots or, in extreme instances, complete lack of hardening may result from attempts to quench badly scaled steel. The remedy is either to descale in some manner before cooling, or more practicably, to carry out the heating operation in a less severely scaling atmosphere. Decarburization may cause nonuniform hardening and other undesirable effects, particularly as reflected in the behavior of the material under repeated or alternating stress (fatigue).

In summary, slower cooling rates yield softer pearlitic structures while rapid rates yield harder, martensitic structures. The pearlitic structures are relatively stable and stress-free; the martensitic structures are quite unstable and are likely to have such high residual stresses as to be unserviceable for most purposes. The question at this point is whether the heat treatment is to be considered completed at the end of the cooling operation or whether a further treatment is necessary. Ordinarily, the softer, pearlitic products resulting from the slow cooling operations require no further treatment, since they are relatively stable from a structural standpoint (although not entirely so). Occasionally the fine pearlitic structures are given a low-temperature subcritical anneal for relieving stress. Such treatment tends to spheroidize the fine lamellar carbides; the extent of spheroidization depends on the temperature and time of the annealing operation. On the other hand, the harder, martensitic products, resulting from rapid cooling or quenching, are usually so unstable and brittle as to be of little practical value in the "as-quenched" condition; hence a further treatment known as *tempering* is almost invariably applied.

Tempering. Fully hardened steel is tempered for relief of quenching stresses and for recovery of a limited degree of toughness and ductility. The operation consists of heating at temperatures lower than the lower transformation temperature (A_1); that is, at temperatures at which the steel is in the ferritic condition. The stress relief and recovery of ductility are brought about through precipitation of carbide from the supersaturated, unstable solid solution (martensite) and through diffusion and coalescence of the carbide while the tempering operation proceeds.

It should be clearly understood that the carbide precipitation which occurs during the tempering of martensite does not take the form of plates, or lamellae characteristic of the pearlitic structures formed directly from austenite during slow cooling; on the contrary, the carbide precipitated during tempering takes the form of a fine dispersion of more or less spheroidal particles, the size of which depends on the time-temperature conditions of the tempering operation. This cannot be emphasized too strongly, since there appears to be considerable confusion on this particular point. No one has ever succeeded in making lamellar pearlite from martensite by a tempering treatment at subcritical temperature.

The higher the tempering temperature or the longer the time at temperature, the coarser the spheroidal carbide particles, and the softer and more ductile the steel. Alloy steels containing the elements that form carbide tend to show greater resistance to softening during tempering than do plain carbon steels; hence, higher temperatures or longer times may be employed in tempering such steels. More thorough relief of quenching stresses is obtained in this way without proportionate sacrifice in hardness.

Some steels are susceptible to embrittlement, or at least to a reduction in ductility, when tempered in the so-called "blue heat" range, or when cooled slowly through this range after tempering. This embrittlement, caused presumably by some precipitation in the steel, can be minimized either by tempering at temperatures lower than the range in which the steel is sensitive, or by cooling rapidly through the range if the tempering temperature is higher.

In general, the tempering operation may be conducted so as to give almost any desired combination of properties by suitable selection of the time-temperature conditions. The correct time-temperature cycle for any given set of properties depends largely on the composition of the steel, and particularly on the composition of the austenite with respect to the amount of dissolved carbon and alloying element that it contains before conversion to martensite by rapid cooling.

Quenching Mediums

BY THE SUBCOMMITTEE ON QUENCHING MEDIUMS*

THE PURPOSE of quenching steel generally is to produce a completely martensitic structure on the surface of the piece to be hardened (a minimum requirement) or in the center of the piece (a maximum requirement). Hardening implies the formation of martensite, which, before tempering, provides the highest hardness obtainable in a steel of low alloy content. This hardness is directly related to carbon content. If the hardening is incomplete, that is, if some pearlite or ferrite is present, usually the mechanical properties will be inferior to those of a completely martensitic steel, even though both are tempered to the same hardness. Accordingly, when highest mechanical properties are required, quenching must be controlled with precision.

Requirements of Liquids for Quenching Determined by the Piece to be Hardened. Whether or not satisfactory hardening is achieved, depends on the composition and structure of the steel, the shape of the piece, and relation between size and section, as well as on the composition of the quenching medium. Because of the complex relations among all these variables, few of which can be expressed quantitatively, hardening remains largely an art. However, failures during hardening can be minimized by recognition of a few well-established relations among hardening variables.

In considering the effects of steel composition and structure, it is necessary to distinguish between shallow-hardening and deep-hardening steels. The shallow-hardening steels are those of low alloy content that remain fine-grained at the austenitizing temperature. Deep-hardening steels contain substantial amounts of alloying elements that promote penetration of hardening. In fact, hardenability is now recognized as a factor so important in heat treatment that special tests for its evaluation have been developed (*see* page 489 in this Handbook).

The fundamental property distinguishing shallow-hardening from deep-hardening steels is the critical cooling rate, which is the slowest cooling rate—measured at about 1020 F—at which a completely martensitic structure can be obtained. The temperature specified is that of maximum rate of reaction in eutectoid carbon steel, established by the "S-curve".[1] For pure iron-carbon alloys of fine grain size the critical cooling rate is extremely high—so high that effective hardening is impracticable. Even in plain carbon steels this rate is high, ranging from 126 to 360 °F per sec. Evidently, then, an extremely fast quench is required for the hardening of shallow-hardening steels. A rapid rate of cooling must be attained at a considerable depth, ⅛ to ¼ in., to assure uniform surface hardening. The cooling rate increases exponentially as the surface is approached, so a very high rate is required at the surface for hardening shallow-hardening steels effectively.

Under favorable conditions, water provides the surface cooling rate necessary for the hardening of carbon steels—approximately 1800 °F per sec. Surface cooling at this rate produces rates within the steel that approach the maximum values theoretically possible to attain.[2] Therefore, water or an aqueous solution is generally used for hardening these steels, which are often identified as "water-hardening" steels. The cooling characteristics of water, however, are markedly affected by a number of variables, which are discussed below.

A necessary consequence of fast surface cooling is a high temperature gradient from surface to center. This gradient, which may exceed 70% of the temperature range (Fig. 1), produces severe distortion in all but simple symmetrical shapes that have a low ratio of length to diameter or thickness. Shallow-hardening steels, therefore, cannot be used in complicated shapes where distortion is objec-

* The members of this subcommittee are Howard Scott, *Chairman* (Westinghouse Electric Corporation), G. T. Williams (Pratt & Whitney Aircraft) and B. F. Shepherd (Ingersoll-Rand Company).

tionable. Furthermore, there is no possibility of changing this situation by the selection of quenching medium, if full surface hardening is required.

Despite the admirable properties of carbon steels, including low price, these steels cannot be used for complicated shapes where distortion must be avoided. For complicated shapes, water quenching should be abandoned

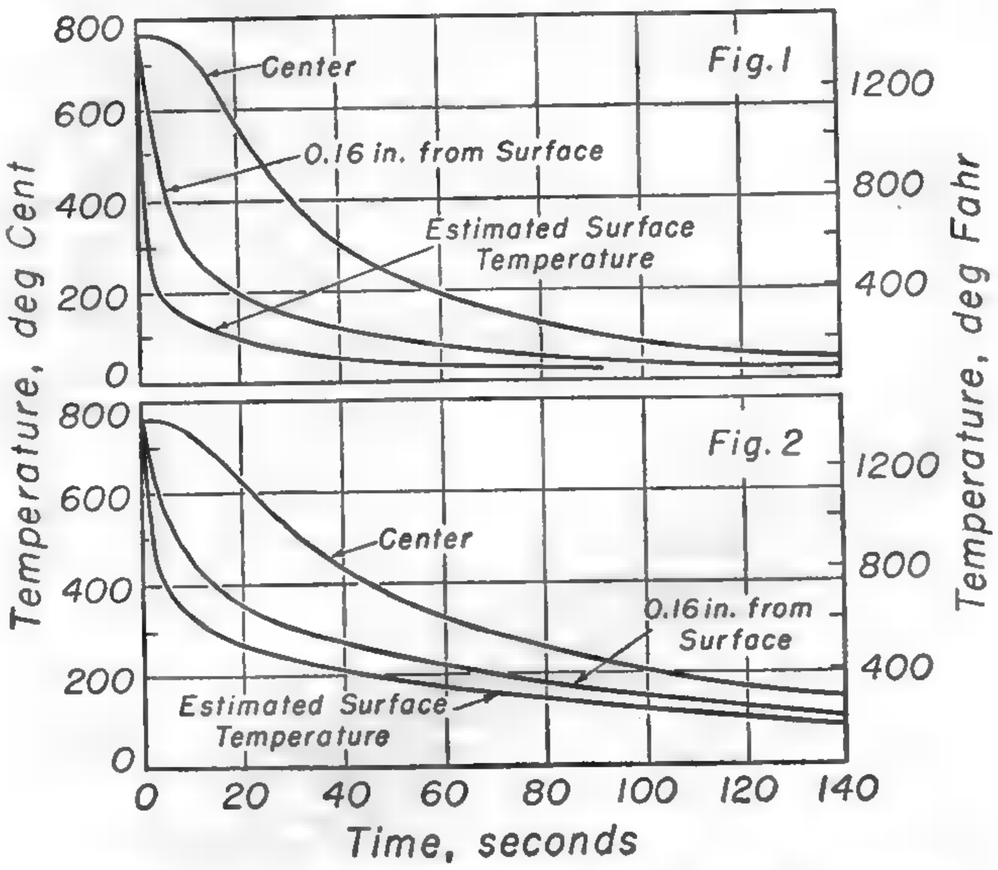

Fig. 1 Observed cooling curve of center and of a point 0.16 in. from the surface of a long austenitic steel cylinder 2.00 in. in diam, during quenching in agitated water

Fig. 2 Observed cooling curve of center and of a point 0.16 in. from the surface of a long austenitic steel cylinder 2.00 in. in diam, during quenching in agitated oil

and a less active quench should be used, which reduces the temperature gradient considerably during quenching (Fig. 2). Certain oils perform this function well, but are incapable of hardening shallow-hardening steels of substantial size. Therefore a drastic change in steel composition is required with a change from a water to an oil quench. Accordingly, steels adapted for deep hardening are often identified as "oil-hardening" grades.

Oil quenching introduces entirely different problems from those of water quenching. Gradients of cooling rate are no longer high, so a completely martensitic surface shell can seldom be obtained over a fully pearlitic core. Usually there is considerable martensite at the center when the surface is fully hardened. If hardening is incomplete at the surface, soft spots are present, which may not be detected easily by a hardness test, but which lower the toughness otherwise obtainable at the same hardness.

Table I. Relative Cooling Rates in Several Mediums[a]

Quenching Medium	Relative Cooling Rate for Diameter of: 1 in.	2 in.	3 in.
Fastest theoretically attainable	1.23	0.30	0.14
Agitated water	1.00	0.27	0.13
Agitated oil	0.48	0.18	0.093
Air stream	0.032	0.0157	0.0102
Still air	0.0152	0.0075	0.0048

(a) These cooling rates apply to the center of a long cylinder made of an austenitic iron-nickel alloy having heat conductivity approximately equal to that of a carbon or low-alloy steel in the austenitic condition.

Since the cooling rate is slower, the larger the section, the alloy content must be increased with increase in thickness of the section. In Table I are listed the cooling rates at the center of long cylinders during quenching in several mediums when the center temperature is 1020 F, compared with the cooling rate of a cylinder 1 in. in diam, quenched in agitated water at a rate of 100 °F per sec. This table shows the major effect of both size and quenching medium on cooling rate and emphasizes the need for adjustment of composition to variations in either.

Residual stresses as well as distortion determine the choice of steel and quenching medium. Water-hardened steels as quenched, are under high compressive stress at the surface and tension in the core,[3] chiefly because the density of martensite is less than that of pearlite. Such stresses, however, are not dangerous, and may even be beneficial, if the core is sound and if no holes bring a surface into the tension zone. Cracks occur under tensional stress only, and hardened steel can support tensional stress that is only a small fraction of the tolerable compressive stress. For these reasons, cracks in water-hardened steels originate in the core or at positions of sharp change in section, except when thin sections harden to the center, behaving then as oil-hardening steels.

Like the temperature gradients from which they originate during quenching, the residual stresses that develop in oil-hardened steels as quenched and fully hardened are lower than the residual stresses that result from water quenching, but more dangerous. This condition arises from the fact that residual stresses in oil-hardened steels are usually tensional at the surface and compressive at the center of the work. This reversal of the expected relations of residual stress arises from the fact that the residual stresses are determined by the temperature gradients during the large increase in volume that accompanies the martensite transformation.[4] Though "set" during this transformation, the residual stress does not reach maximum magnitude until the work is cold, which accounts for cracks occurring at atmospheric temperature.

Cracks developed by oil quenching are widest at the surface and penetrate deeply, a characteristic distinguishing them from the relatively shallow cracks caused by decarburization or grinding. Oil-quenching cracks are common only in moderate size. Residual stresses in small sections are low because temperature gradients during hardening are also low. As thickness of section increases, the surface stress tends to revert to compression, thus reducing the danger of cracking in heavy sections also.

Since the martensite transformation occurs at relatively low temperatures—starting usually in the range from 900 to 400 F and depending chiefly on carbon content—cooling rates are then low, and the temperature gradients that determine the residual stress are accordingly subject to some control. An ideal quenching medium would cool very slowly in this range, but would cool as fast as desired at the temperature of maximum rate of reaction, 1020 F. Oil is a great improvement over water in this respect, but is still far from ideal. Several expedients by means of which both distortion and residual stresses can be reduced to a minimum are discussed on pages 619 and 620.

Liquids for Quenching Shallow-Hardening Steels. Pure water, adequately agitated, meets effectively the requirements for extremely fast surface cooling demanded by shallow-hardening steels. A submerged water-spray quench, for example, appears to offer the fastest practicable surface cooling and to be highly reproducible as well. In application, however, this quench is definitely limited to simple short objects not likely to warp. Because of the difficulty in obtaining symmetrical flow of the water in relation to the work material, the spray quench is highly conducive to warping. The ideal fast quench is therefore one that will cool the surface as required, without any agitation of the bath.

It has been shown that concentrated sulfuric acid approaches this ideal.[5] However, sulfuric acid is too dangerous a liquid for practical use. Ordinary tap water, without agitation, is a poor substitute that will not harden the material consistently, with freedom from soft spots. The addition of common salt (sodium chloride) greatly improves the performance of unagitated water, as will be shown presently. The manner in which it improves performance can be seen clearly from a consideration of the variation in the mechanism of heat extraction with change in surface temperature.

By plotting cooling curves for a small specimen during quenching, Pilling and Lynch[6] determined how the power of the liquid to cool the surface changed with the surface temperature of the piece. Their observations are highly significant in that they show three distinct mechanisms of heat dissipation, which have been verified by Speith and

Lange.[13] Figure 3 is a typical curve illustrating the three stages of cooling, which have been described by Scott[5] as follows:

Stage A. Vapor Blanket Cooling. In this, the first stage, a thin stable vapor film surrounds the hot metal. Cooling is by conduction and radiation through the gaseous film and is therefore relatively slow.

Stage B. Vapor Transport Cooling. Termination of the *A* stage is marked by the wetting of the metal surface. Vapor forms copiously in bubbles and is carried away by gravity and convection currents to condense in cooler surrounding liquid. This is the fastest stage of cooling.

Stage C. Liquid Cooling. The *B* stage ends when the surface temperature of the metal approaches the boiling

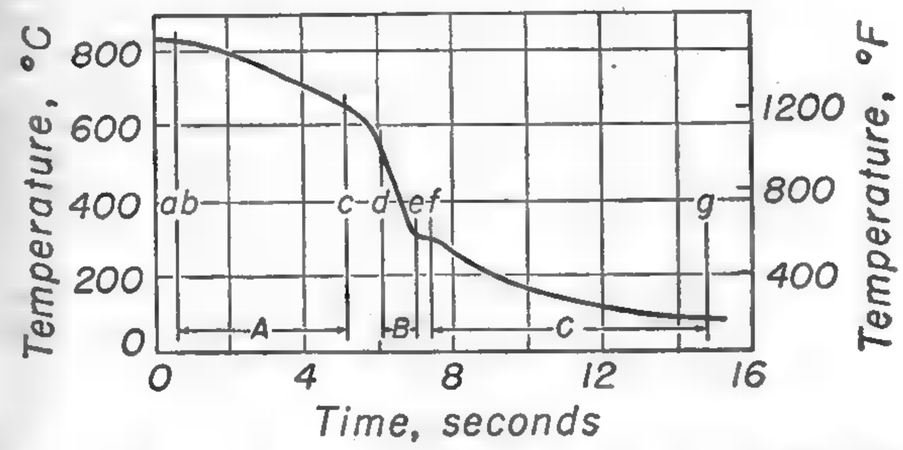

Fig. 3 Typical cooling curve for the center of a small cylinder during quenching in still water at 137 F, illustrating the three stages of surface cooling (Scott[5])

point of the quenching liquid. Vapor no longer forms, so cooling is by conduction and convection and the difference in temperature is greatly decreased. This mode of cooling is slower than that of the *B* stage.

Cooling in the *B* and *C* stages is in fair accord with Newton's law of cooling; that is, the cooling rate is proportional to the surface temperature, which holds closely for short temperature ranges.[2] In the *A* stage, however, cooling is at a nearly constant rate, decreasing somewhat with increase in the bath temperature.

Zavarine has noted from photographs made at high speed that bubbles collapse at a relatively slow rate in the *A* stage and extremely fast in the *B* stage, vanishing in the *C* stage; and that crystals of salt are precipitated momentarily during quenching in brine.

There has been much debate concerning which of the fundamental properties of liquids determine the quenching power. Properties mentioned include thermal conductivity, viscosity, specific heat, and heat of vaporization. Evidently, which property is dominant depends on the stage concerned. Certainly boiling point is a major factor in the *A* stage, heat of vaporization in the *B* stage, and thermal conductivity in the *C* stage. Viscosity also contributes to cooling power in both the *B* and *C* stages. Each stage has an important part in determining the success of a quench. No distinction has been made between the *A* and *B* stages in the data of Table II; the column at the left represents a combination of both stages, the column at the right represents *C* stage cooling only. As a consequence of this overlap, water at 120 F, for example, is placed below certain oils, though its cooling rate in the *B* stage is just as fast as that of the LiCl solution. The three stages have been distinguished sharply in Table IV.

The vapor stage, *A*, is of most concern in water solutions. Cooling is slow in this stage, and if it persists for more than a few seconds, transformation will occur at Ar_1, producing soft spots. To avoid such transformation, the vapor stage must be suppressed or nearly so. The duration of the vapor stage may be measured in time units on the quenching curves plotted by Pilling and Lynch, giving a quantitative measure of the extent to which the vapor stage is suppressed (Fig. 4). This figure shows that the duration of the vapor stage in water and water solutions increases rapidly with temperature of the bath; hence the first rule of quenching is: Keep water-base quenching liquids cold, preferably below 70 F.

Figure 4 also shows clearly why salt is an advantageous addition to water; it greatly reduces the duration of the vapor stage, particularly at elevated temperatures. The liquid adjacent to the work material is, of course, much above the average temperature of the bath. The best concentration might then appear to be a saturated solution, about 26%, but the disadvantages of so high a concentration have been demonstrated by tests on solutions in which the content of solute was varied systematically.

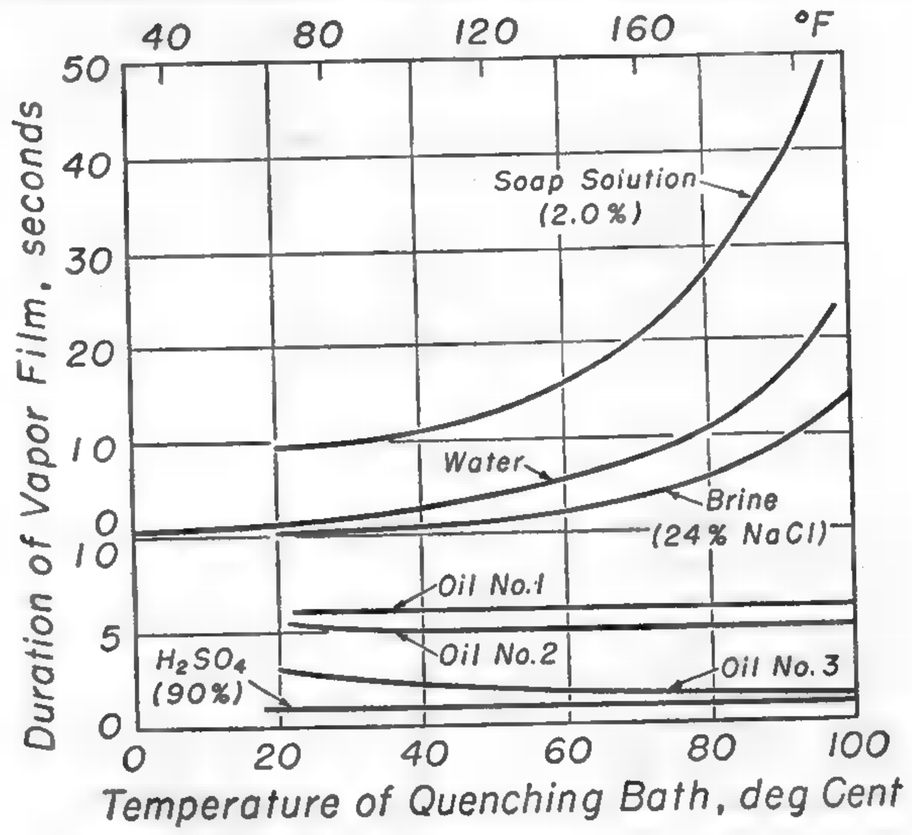

Fig. 4 Duration of the vapor-film stage of surface cooling during quenching in several liquids (Pilling and Lynch[6])

Brine (sodium chloride) and caustic soda (sodium hydroxide) solutions are used extensively for their beneficial effect in reducing the duration of the vapor, *A*, stage.

Table II. Cooling Rate at the Center of a 4-mm Diam Nichrome Ball Through the Temperature Range 1328 to 1022 F During Quenching in Various Mediums from 1580 F[10]

Quenching Medium	Cooling Rate Relative to that for Water at 65 F[(a)] 1328 to 1022 F	At 392 F
Aqueous solution 10% LiCl	2.07	1.04
Aqueous solution 10% NaOH	2.06	1.36
Aqueous solution 10% NaCl	1.96	0.98
Aqueous solution 10% Na_2CO_3	1.38	1.09
Aqueous solution 10% H_2SO_4	1.22	1.49
Water at 32 F	1.06	1.02
Water at 65 F	1.00	1.00
Aqueous solution 10% H_3PO_4	0.99	1.07
Mercury	0.78	0.62

(a) Cooling rate for water at 65 F is 3260 °F per sec through the range from 1328 to 1022 F, and 810 °F per sec at 392 F.

Optimum concentrations of these two compounds have been found by tests to be effective in avoiding the formation of soft spots in steels that have a strong tendency to harden irregularly.[14] Regardless of the temperature of the quenching solution, from 75 to 140 F, 9% NaCl or 3%

NaOH gave minimum soft spots; effectiveness decreased as the temperature increased. With a temperature in the upper part of this range, 9% NaCl was somewhat more effective than 3% NaOH; when the temperature was kept below 120 F, either gave better results than plain water at 75 F. The lower the temperature of the solution, the less critical was the concentration, although the certainty of local heating of the bath during quenching makes it desirable to control the composition of the bath carefully. Concentration may be checked readily with an ordinary hydrometer of suitable range. Table III gives relationships between concentrations of these two compounds and the hydrometer readings for solutions tested at 68 F.

5	1.0538	7.4	0.4397

Brine is used more widely than caustic soda, although brine creates problems by promoting rapid rusting of handling equipment and of the steel being quenched. Sodium hydroxide solutions have a protective influence against rusting, but such solutions offer more hazard to the operator, because contact with the skin is painful unless the solution is promptly washed off. Since the eyes are especially sensitive, goggles should be worn.

Although certain concentrations of some other inorganic compounds have a beneficial effect on quenching, there appears to be no merit in using them. Many materials soluble in water have a detrimental effect; soap is especially undesirable, because it extends the duration of the *A* stage and therefore acts in the same manner as an increase in the temperature of water (Fig. 4). Therefore, hands must not be washed in quench tanks, and no other contamination should enter the water or solution.

Mixtures of water and "soluble" oils, such as are used for coolants in machining, are occasionally used for quenching, but rarely give satisfactory uniformity of hardening. The mean cooling rate of such mixtures for *A* and *B* stages is lower than for most plain oils (Table II). However, a 10% mixture is sometimes used for cooling the work material quickly after tempering, because of the rust-delaying film thus produced. When steel hotter than about 900 F is cooled in such a liquid, the surface is darkened and a thin film of oil is retained, so this treatment is occasionally given to bolts and such after tempering or annealing below the transformation range.

Liquids for Quenching Deep-Hardening Steels. Deep-hardening steels are used in order that a fully martensitic structure may be obtained with an oil quench and therefore without excessive distortion.

The vapor-film stage of cooling, *A*, is less important in oil than in water quenching. Actually, the vapor stage may persist longer (see Table IV) but is not harmful unless exceptionally long, because the rate of cooling is faster in this stage with oil than with water, and the critical cooling rate of an oil-hardening steel is slower than that of a water-hardening steel. The duration of the vapor stage is longer, the lower the boiling point of the oil, so some lower limit should be placed on the boiling point of the oil used. Of course, the boiling point of oil is rather indefinite and must be defined arbitrarily.

The boiling points of the oils listed in Table IV are so high that moderate increases in temperature of the oil have little effect on the duration of vapor-film cooling. Consequently, oils, unlike water solutions, can be used while warm, without danger of incomplete hardening and with advantages in some respects. The cooling power of warm oil in the *B* stage is actually higher than that of cold oil. This is undoubtedly a result of lowered viscosity, which permits more rapid movement of vapor in carrying heat away from the metal surface. However, a real advantage in using warm quenching oil arises from consideration of residual stresses.

There is danger of cracking deep-hardening steels by cooling rapidly into the martensite transformation, as already shown. This transformation occurs during cooling, usually in the *C* stage. If cooling in this stage can be slowed down considerably, the steel will be less likely to crack. In this respect, cold oil has an advantage over water (*see* Table IV). The cooling rate in the *C* stage of oil is about 1/10 that in the *B* stage, while with water the ratio is about 1 to 6.5. However, the major advantage of oil is that the temperature can be raised considerably without bad effects, thereby lowering decidedly the cooling rate just above the martensite transformation range.

Caution is needed when warm quenching oil is used, except under careful control of temperature. The oil should not be so hot that it flashes or burns after the work material is immersed, thus becoming dangerous to the workmen. However, oil should not be used when below 90 F, because of the hazard of cracking certain steels. The usual types of quenching oil operate best when the temperature of the oil near the work being quenched is maintained between 90 and 140 F. Good circulation of oil is imperative (1) to eliminate stagnant pockets where stage *A* may persist long enough to produce incomplete hardening, (2) to maintain temperature uniformity, and (3) to dissipate heat from the work.

Table IV. Cooling Rates at Center of ¼-in. Diam Cylinder of Nickel-Base Alloy During Quenching in Still Liquids at 104 F, Showing Variation in Cooling Action with Surface Temperature of Pieces.[6]

(a) Cooling rates in *A* stage taken at 1472 to 1292 F; in *B* stage at 1022 F; and in *C* stage at 392 F

So far only general qualities of oils have been considered. Among the numerous compositions available, it is difficult to be specific about the selection of an oil. The only suitable way of identifying quenching oils is by the physical properties of them and only a few investigators have recorded identifying properties, notably those whose data are given in Tables IV and V.

It has been shown[15] that oils over ■ wide range of viscosity at room temperature, when heated to an optimum temperature for each oil, give almost identical cooling curves. By varying the temperature of the oil, it is possible to change the cooling rate from a low value to one approximating that of the best oil under best conditions. The use of hot oil introduces not only the obvious problems and hazards but also the danger that the martensite transformation will be incomplete and that austenite will be retained, unless the work is further cooled after quenching and before tempering; therefore it is good practice to use an oil that gives the maximum quenching rate when maintained at 90 to 140 F. A low-priced straight mineral oil with Saybolt viscosity of about 100 at 100 F, is generally used.

Compound oils, having additions of special fatty or petroleum derivatives, have been developed to give faster

cooling than the plain mineral oils, and are particularly useful where the quenching system or the hardenability of the steel is inadequate. The use of such oils, however, is not a satisfactory substitute for proper control of temperature and circulation of quenching oil. Compound oils should be considered as possible improvements when cooling practice is already good.

Water gives quenching oil a murky or red appearance and causes irregular quenching rates. Consequently, contaminated oil should be replaced, and the cause, such as leakage from cooling coils or splash from adjacent water tanks, should be eliminated.

Standard tests, such as those of which the results are shown in Tables IV and V, are probably inadequate to determine the necessary qualities in quenching oils. The list of standardized tests of oils given in Table VI is probably sufficiently inclusive to assure duplication of good quenching properties found in a particular oil.

The standard tests are also important in regard to secondary requirements of quenching oils. Low viscosity assures free draining of oil from the work material and consequent low loss of oil. A high flash and fire point assure a high boiling point and reduce the fire hazard, which is increased by keeping the oil warm. A low pour test assures ample viscosity when cold. A minimum carbon residue suggests stability of properties and little sludging with continued use. The steam-emulsion number should be low to assure minimum water content; water is objectionable because of its great cooling power and its tendency to form a vapor film. A low saponification number assures that the oil has a mineral base and is not subject to organic deterioration, which causes offensive odors. The viscosity index is a valuable property for maintenance of composition.

Tests for these properties are suggested, however, only as a means for maintaining the composition of an oil found to be satisfactory by experience. Stability and reproducibility of properties are perhaps the most important requirements for quenching oils. It is important also to permit no deposit of sludge on cooling coils. Films of salt on tne work—for instance, when it is being quenched from a fused cyanide bath—are detrimental to oil.

Table V. Cooling Power and Other Properties of Various Oils[a]

Efforts have been made to secure in water-base liquids quenching characteristics equivalent to those of oil. This is an admirable objective but so far the attempt has been entirely unsuccessful. Rates similar to those obtained during cooling in oil, can be secured in particular temperature ranges, but not through the whole temperature range of quenching; that is the reason for the difficulty. Scott,[8] for example, shows that a mixture of glycerin and water will give a cooling rate in the *B* stage which is the same as that of a popular proprietary quenching oil. The cooling power of this liquid in the *C* stage, however, is much faster than that of oil; this condition is highly objectionable because of residual stresses. The same objection applies to solutions of ethylene glycol and sodium silicate in water. Also, the duration of the *A* stage in all these liquids is increased by the presence of water, which endangers completeness of hardening.

Emulsions of oils in water also have been used as quenching mediums, although the characteristics are even worse than those of the solutions just mentioned. In the *A* stage, cooling is greatly extended, and in the *C* stage, cooling is virtually as fast as in water. This reversal of the ideal relations between the stages is shown clearly in Table II. It is unlikely that a water-containing substitute for quenching oil will be developed soon.

Quenching Mediums for Minimum Distortion and Residual Stress. Quenching in oil is much more satisfactory than quenching in water as far as distortion is concerned, but even in oil, distortion may be quite severe in thin or complicated sections of pieces like many that are used by the aircraft industry. Also, cracking is a hazard in critical sections. These problems associated with quenching in oil, have been solved to some extent by the practice of supporting work material on trays during quenching. The trays are automatically oscillated vertically in the oil bath, which in turn is agitated chiefly by the movement of the work material. This symmetrical cooling, in combination with judicious placement of the work material, achieves consistency in dimensional changes, as well as a reduction in the magnitude of these changes. Commercial furnaces are available for quenching steel under a protec-

tive atmosphere so that the work material is removed from the quench free from scale and decarburization.

To harden steel without measurable distortion or residual stress, it is necessary to use a much slower cooling medium than oil—for example, a gas. This expedient requires a steel of exceptionally high alloy content and consequently high cost, both of metal and of machining time. The additional cost is well justified, however, in producing expensive and intricate tools or dies.

Many steels designed for hardening in gas are now on the market. They are identified as air-hardening steels but can be hardened as well or better in protective atmospheres. For example, in one commercial furnace the work material is surrounded by dissociated ammonia during the cooling as well as the heating period. Though this gas has a thermal conductivity considerably higher than air, actual cooling rates are no faster at high temperatures, because of lower emissivity of heat, resulting from the bright surface maintained through the cycle. This atmosphere, if maintained at the high state of purity at which it is generated, prevents decarburization as well as oxidation, and even permits bright hardening of stainless steel.

Results approximating those obtainable with gas-hardening steels can now be attained consistently with the less expensive oil-hardening grades by the use of "martempering".[11] The work material is quenched in a liquid at or close to 400 F. The liquid is preferably a molten salt that has cooling properties similar to those of quenching oils. Oil having a high flash point may be used also, if covered by a suitable protective atmosphere. Work material is removed when it approaches the temperature of the bath, and is then cooled in still air to atmospheric temperature, with precautions to minimize temperature gradients.

Martempering is very effective in controlling residual stress by reduction of temperature gradients during the martensite transformation. Particularly important is the elimination of temperature differences between heavy and light sections while in the quench bath, before transformation starts or is well advanced. The martensite transformation starts at approximately 400 F in high-carbon steels, but at progressively higher temperatures as the percentage of carbon in solid solution at the austenitizing temperature is reduced. For this reason martempering is less effective when applied to low-carbon steels than to high-carbon steels, though this process is considerably more satisfactory than a conventional quench, because of reduction in cooling rate in the range from 900 to 500 F as a result of the high terminal temperature, 400 F. This treatment should not be confused with austempering, which permits the transformation of austenite to go to completion at the holding temperature. In martempering, the aim is to complete the transformation of austenite to martensite during air cooling to room temperature.

The Quenching Process and Industrial Quenching Equipment

BY THE SUBCOMMITTEE ON QUENCHING*

MANY treatments for steel involve cooling the metal from an elevated temperature. This article discusses only the processes of cooling steel during the hardening operation. Such quenching processes include accelerated cooling by either liquid immersion, gas or liquid agitation, or contact with a cold metal.

Great progress has been made in the development of modern equipments to heat steel properly. The equipment to remove the heat properly has received far less attention. Recently there has been closer study of the hardenability of steel and, consistent with this trend, has been a greater interest in the cooling rates that may be obtained in quenching processes.

The purpose of this article is to outline the underlying metallurgical and thermal aspects of quenching and to describe the factors entering into the design and use of modern industrial quenching equipment.

Metallurgical Aspects of Quenching. The general principles of the heat treatment of steel are discussed in the article on page 613 of this Handbook.

In a metallurgical sense, the effective quenching of steel consists of cooling austenite through the transformation range in such a manner as to allow the formation of martensite, which is hard, and to prevent the formation of ferrite or pearlite, which are soft. The "critical cooling rate" is the slowest that will accomplish this result.

The maximum hardness obtainable in steels cooled at a rate equal to or greater than the critical rate, depends on the carbon content, in the manner shown in Fig. 1.

When the cooling rate is less than the critical rate, transformation to ferrite, pearlite, or bainite takes place with a corresponding decrease in the amount of martensite formation and a lower resultant hardness. When the cooling rate is such that only 50% martensite is formed, the resultant hardness versus carbon content for medium alloy and plain carbon steels is that shown in Fig. 2.

When plain carbon steel is quenched from the correct austenitizing temperature, the critical cooling rate is 100 to 360 °F per sec, measured at 1300 F. Therefore, the steel must cool at least as fast as this throughout the entire cross section of the piece if full hardening is to be obtained. Water, under favorable conditions, provides cooling rates of approximately 1800 °F per sec at the surface. Cooling the surface at this rate produces cooling rates throughout the cross section at about the maximum theoretically attainable. Hence, for relatively light sections, where the ratio of surface to volume is large, extremely rapid cooling throughout can be obtained by a quenching method that cools the surface rapidly, as in water quenching. In such instances plain carbon steels with more than about 0.35% C, although possessing relatively high critical cooling rates, may be fully hardened.

A necessary consequence of fast surface cooling as obtained in water quenching, is a high temperature gradient

Aittama (Wisconsin Axle Company), W. J. Bornholdt (Caterpillar Tractor Company), G. W. Bornquist (Bell & Gossett Company), John D. Graham (International Harvester Company), Frank O. Grubel (Paterson, N. J.), H. W. Lange (Cardox Corporation), W. Lehrer (Surface Combustion Corporation), A. P. Seasholtz (Seasholtz Metallurgical Service), R. H. Swartz (Ordnance Steel Foundry) and F. F. Vaughn (Caterpillar Tractor Company).

from surface to center. This produces severe distortion and the hazard of cracking in all but simple, symmetrical shapes that have a low ratio of length to diameter or thickness. Under favorable conditions, oil quenching provides a cooling rate at the surface of approximately 135 °F per sec as compared with 1800 °F per sec with water; hence a much lower temperature gradient from surface to center. Steels with high critical cooling rates requiring a water quench, should therefore not be used in complicated shapes or nonuniform sections where distortion is objectionable. Such parts require alloy steel with a low critical

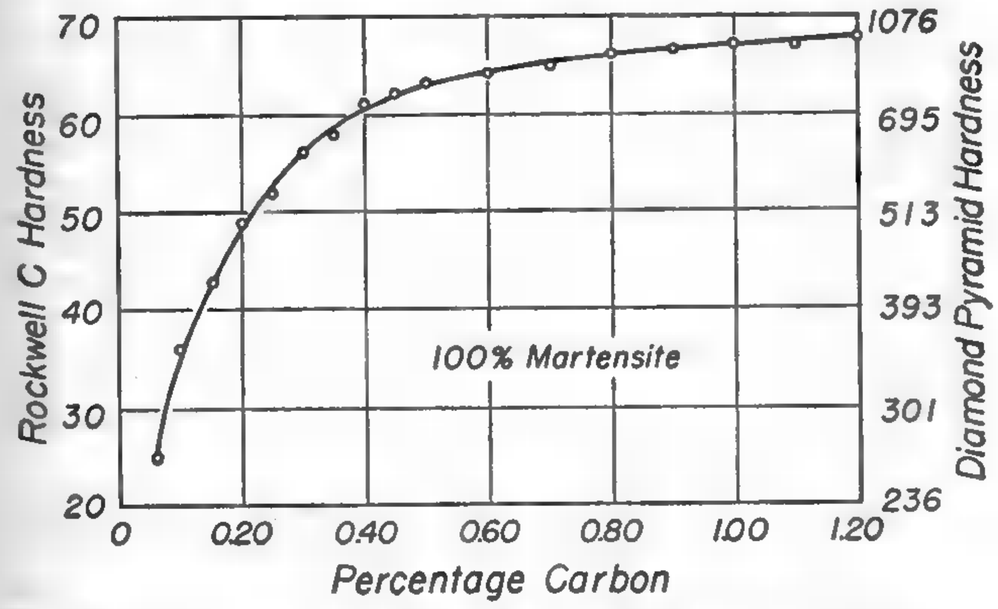

Fig. 1 Influence of carbon content on the hardness of fully martensitic steel, as quenched

cooling rate, which may be attained throughout the section in an oil quench, thus reducing substantially the temperature gradient during quenching.

With heavy sections, the cooling rate is limited by the rate of conduction of heat from the interior to the surface. Hence it becomes impossible to cool the center of a large section rapidly by any quenching method, because of "mass effect". For full hardening of heavy sections, it is necessary to use steel that contains a sufficient amount of alloying elements to lower the critical cooling rate to equal that attainable at the center by oil quenching.

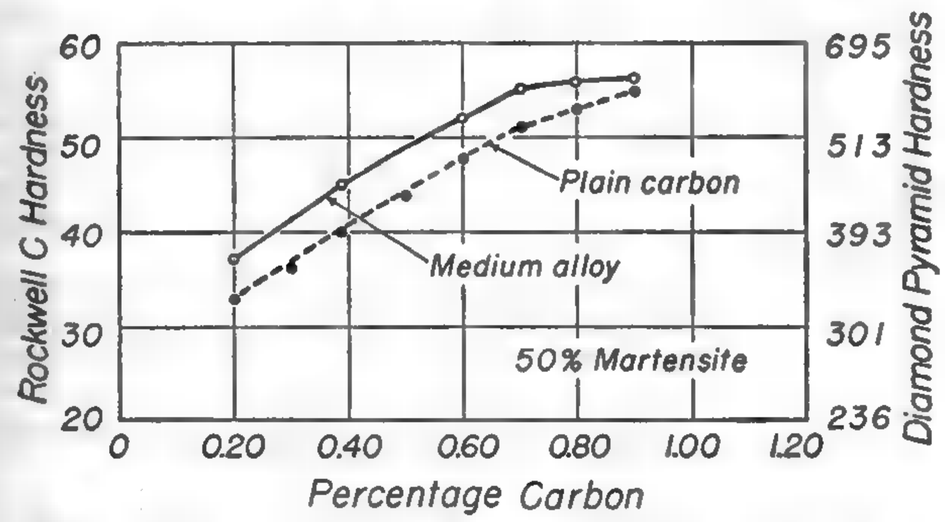

Fig. 2 Influence of carbon content on the hardness of steel that contains 50% martensite, as quenched

The term "hardenability" is used for describing the relations between cooling rate and depth of hardening. For information on hardenability testing, see page 489.

Physical and Thermal Aspects of Quenching. In addition to metallurgical transformations, certain thermal considerations are important in the quenching process.

Since heat can be removed from a solid object only by dissipation from the surface, the rate of cooling depends on the temperature of the surface of the object during the quenching process. The shortest possible time of cooling is obtained when the surface is at the temperature of the cooling medium. The decreased surface temperature necessary to promote rapid cooling may be obtained by bringing the cooling medium into contact with the surface of the object. The rate of cooling produced depends on the temperature, mass, and shape of the object, the inherent characteristics and speed of circulation of the quenching medium, or the speed of movement of the object being quenched. Whether or not hardening occurs during a particular cooling operation depends, of course, on the composition of the steel, as well as on the quenching medium.

Elements of the Quenching System. The following functional equipments are usually required and installed for a suitable quenching system: (1) work tank or machines, (2) facilities for handling the parts quenched, (3) quenching medium, (4) agitation, (5) coolers, (6) heaters, (7) pumps and strainers, (8) supply tank and (9) equipment for ventilation and for protection against hazards.

Just how elaborate a quenching system should be depends on many factors—primarily on the hourly production, the accepted quenching technique, and the justification of the initial cost. For example, a small plant making machine parts might require the hardening of a few small pieces per day in the as-forged condition, parts that weigh 3 lb each and are made from 1045 steel. A satisfactory

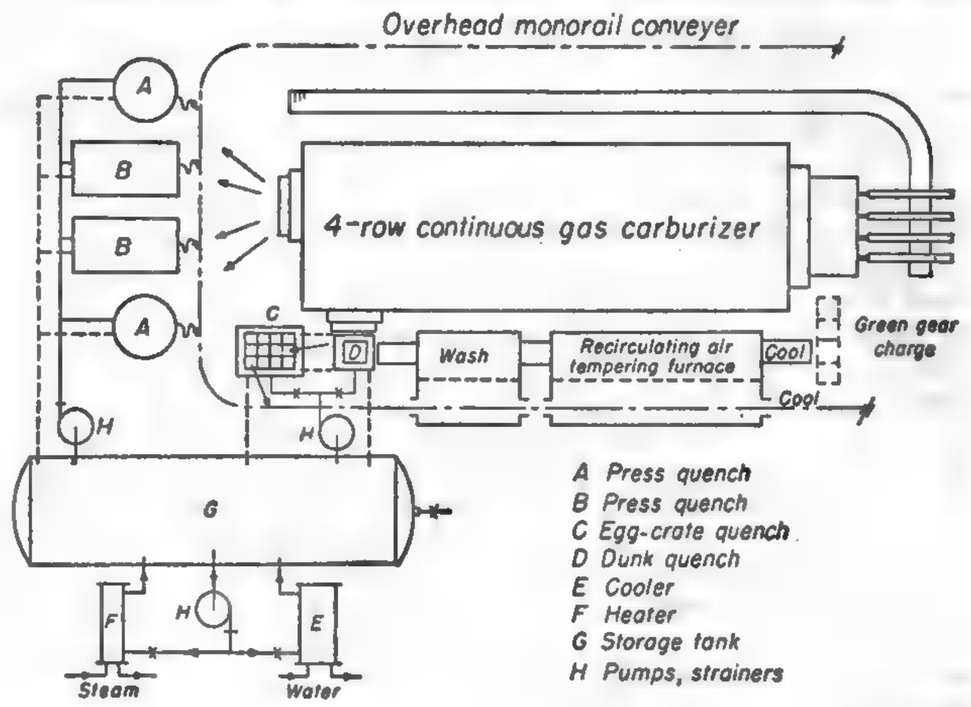

Fig. 3 Layout showing the elements of a quenching system

quenching system for this requirement would involve a barrel of water with piping for the supply, and a gravity drain to a sewer. The work would simply be removed from a furnace with tongs and immersed in the water.

In contrast with this simple setup is an automotive plant manufacturing rear-end assemblies. The problem is to quench carburized gears in large-scale production. There are several models of assembly and each requires a ring gear, stem pinion, differential side gears and differential pinions. Gears weigh from less than 1 lb to 10 lb each. All must be processed efficiently in order to match the final requirements of the assembly line. The as-quenched gears must meet close inspection for metallurgical and mechanical properties. Since a low cost per unit must be maintained for the whole heat treating operation, the quenching process is integrated with the heat treating equipment, and handling facilities are laid out accordingly.

Green gears, fully machined except for finish grinding, are charged into a continuous pusher-tray type of gas carburizer. Work pieces are loaded on alloy trays with suitable fixtures that permit direct quenching.

The following elements, as shown in Fig. 3, might comprise the quenching system for such an operation:

1 Work tanks and machines
   - *a* Quenching press for one model of ring gear
   - *b* Quenching press for another model of ring gear
   - *c* Special "egg-crate" quenching tank for stem pinions
   - *d* Special "dunk tank" for quenching side gears and differential pinions without removing from trays or fixtures

2 Handling facilities
   - Special "peel" to remove hot ring gears from a tray in the furnace to the gear presses
   - *b* Overhead conveyer for washing, tempering, cooling and inspection
   - *c* Hooks to remove hot stem pinions from tray to "egg-crate" quench (Pinions would then be placed on an overhead conveyer for subsequent processing.)
   - *d* Alloy trays and fixtures to immerse trays of differential side gears and pinions directly into the "dunk tank". (From here the trays and work pieces go directly to the washing, tempering, cooling and inspection operations.)

3 Quenching medium, a properly selected oil that will provide consistently the desired rate of cooling.

4 Agitation
   a Special provision for agitation is taken care of in the quenching presses themselves
   b Pump to supply proper circulation of oil to the "dunk tank" as well as the special "egg-crate" work tanks
5 Coolers and heaters to maintain a definite temperature of the quenching oil, whether starting from shut-down or working under continuous production conditions
6 Pumps and supply tanks as noted in Fig. 3

Factors Determining the Design of Work Tanks. *Study of Parts.* The laying out of work tank equipment for the quenching operation should start with a study of the parts to be manufactured. All steps of manufacturing are normally established from the print for the parts, and equipments, including work tanks, are selected to handle the required production schedule.

The following information is immediately available from the print for the parts: (1) size, (2) shape, (3) weight, (4) section, (5) steel used, (6) hardness specified and (7) tolerance allowed.

Technique of Quenching. The technique of quenching may be defined as the method employed in applying the work piece to the quenching medium, or the quenching medium to the work piece, to produce desirable metallurgical and mechanical properties in the steel in the as-quenched condition. This, of course, must be accomplished without excessive cost and with suitable handling facilities.

With the above-mentioned information on the parts, the next step is to determine what quenching technique is to be used for treating the parts. Past experience is helpful and there are many "rules of thumb" that may indicate what methods are practicable. Conversely, other methods may be ruled out on the basis of experience. If the part is new and of such size and shape that it does not conform to past experience and practice, then tests should be made to determine what quenching technique is required.

In addition to the necessity for the quenching process to remove heat from the work piece rapidly enough to impart the desired metallurgical and mechanical properties to the parts, consideration must be given also to thermal factors such as the following:

1 Mass determines the amount of heat removal.
2 Exposed surface area influences the rate of cooling.
3 Thermal differential between work surface and quenching medium influences the rate of cooling.
4 Depth of metal section determines the duration of quench.

Items 1, 2 and 4 are fixed by the design of the work piece. Item 3 introduces the subject of agitation.

Agitation. Agitation may be defined as the mechanical means employed to accelerate relative motion between the work piece and the quenching medium, thereby ensuring a high thermal differential between the surface of the work piece and the quenching medium. Practical experience has shown that accelerated rates of heat abstraction from quenched steel are possible by means of forced circulation or agitation. Thus over-all quenching efficiency is improved and full benefit is derived from the use of the steel so quenched and of the medium employed.

After entering the liquid quenching medium, the hot steel is cooled in three stages, known as "vapor blanket cooling", "vapor transport cooling" and "liquid cooling".*

Agitation of the liquid quenching medium against the hot steel accelerates quenching, especially during the "vapor transport" stage of cooling. Liberal circulation keeps the temperature of the quenching liquid more uniform and thus increases the efficiency of quenching. Agitation also keeps the surface temperature of the work piece uniform during the final stage of quenching, which tends to equalize quenching strains that would otherwise cause distortion of the steel.

It might be asked: if a little agitation is good, is a lot of agitation better? And if so, what determines the volume of circulation to be employed for the average work tank? In the entire subject of quenching, these are probably the simplest and most direct questions to ask, and the hardest to answer satisfactorily.

It can be stated that the volume of circulation or agitation to be provided in the work tank depends on (1) size, shape and surface area of work piece, (2) type of medium used, whether it is rapid or slow in its quenching speed, (3) steel used, whether shallow hardening or deep hardening, (4) hardness and other properties required, (5) allowable distortion, (6) temperature uniformity of quenching medium in the work tank, (7) surface condition of work as it enters the tank and (8) rate of production.

Some of the above points are self-explanatory. A heavy section of deep-hardening alloy steel is often quenched in water with generous agitation when treated in the "rough". The part is then tempered and full-finish machined as a means of eliminating distortion. This is common practice, for example, in the treatment of axles and splined shafts.

On the other hand, if the part to be quenched is a fairly large axle or splined shaft that is carburized, it must be full-finish machined except for dimensional finish grinding. Such a part should be immersed vertically in a still medium, with no agitation for the first few seconds of immersion, so that a hardened "crust" will hold the shaft in alignment. Then a heavy volume of agitation is applied to remove the heat from the center of the piece in order to develop the properties desired in the core.

Agitation can be produced in several ways. In conventional work tanks, circulation is usually provided by pumps, by agitators or by the gravity fall of the piece through the quenching medium.

Pumps are perhaps most commonly used, since they provide a flexible means for directing the quenching medium where it is most effective. Also, the flow can be split to provide circulation to one or more locations in the tank with easy adjustment. When the medium is oil and a cooler is used, the same pump that forces liquid through the cooler can often act at the same time as an agitator pump. In special work tanks that involve a "floating fountain" quench, or in a design that requires the rapid removal of heat from a cavity of the work piece, the recirculating pumps may be the preferred equipments for producing agitation.

Agitators with mechanical propellers are popular and effective in producing general agitation in a conventional work tank. The self-contained mechanical agitator is compact, requires no piping, and is easily removed for maintenance. Other forms of driven propellers are excellent, although they must be properly located in the work tank in order to function effectively.

The third method of agitation depends on the gravity fall of the hot piece through the liquid. This method is usually employed in quenching light parts that have high surface area per unit weight. If pumps or mechanical agitators were used, the work piece would probably drift undesirably in the tank and it would be difficult to handle the load with a conventional elevator-conveyer discharging work tank.

There are other instances where the work piece is driven mechanically with respect to the quenching medium. Shafts, for example, are sometimes rotated in the quenching medium, in order to produce the effect of agitation.

Several of the methods of agitation just described may be combined in the design of a single work tank.

Practical Suggestions for the Design of Work Tanks

1 The time necessary to "quench out" the part treated, should be measured, and allowance should be made for this cycle when the hourly rating or capacity of the work tank is determined. When this factor is considered and the mechanism determined that provides for the desired quenching technique, the size of the enclosure of the work tank follows. This volume of medium is then used in other calculations concerning equipment and in the selection of size; for example, the volume of medium influences the selection of the size of cooler and whether a supply tank is necessary, as will be explained later.
2 Adequate space should be provided around the work piece in order to get the full benefit of circulation and maximum heat absorption from the quenched parts.
3 At best, it is difficult to control distortion caused by thermal strains when quenching. Therefore, the hot and plastic work piece should not be mutilated and deformed by allowing it to fall on the chute or quench conveyer until sufficient quenching has taken place to form a hard crust that will protect the part. On the other hand, if the part is large enough not to be deformed by such handling, premature destruction of the chute and conveyer mechanism is likely to result.
4 The work tank should be accessible to facilities for maintenance and cleaning.
5 If removal of scale from the tank is a serious problem, the use of a furnace that has a controlled atmosphere should be considered.

* These three stages of quenching are discussed in the article on page 615.

6 If caustic or brine is used in the work tank, ventilation should be provided in order to protect workmen from fumes and to improve working conditions.
7 If the quenching medium is oil, protection against fire hazard should be provided.
8 The use of clean-out plates on the work tank should be avoided unless otherwise necessary. The gaskets are difficult to maintain and will leak unless many studs are used on closely spaced centers.
9 It is possible to use almost any mechanism in the work tank when oil is the quenching medium.
10 Special selection of materials for mechanisms is usually necessary if brine or caustic is used. A high cost of maintenance will usually result.
11 Alloy trays and fixtures of the 25 Cr – 12 Ni or 35 Ni – 15 Cr type can be quenched in oil quite satisfactorily, but not in water, caustic or brine.
12 If water, caustic, or brine must be used, the use of special materials for pumps, coolers, and other equipment, should be considered.
13 Wherever possible, the design of the work tank should provide for flexibility and control of such conditions as: (*a*) time cycle of quench, (*b*) volume of circulation and (*c*) uniformity of bath conditions.
14 It should not be expected that agitation will solve all problems. Excessive agitation that will blow light parts off the conveyer and thereby lose them, should not be employed. A medium that has a higher speed of quenching should be used instead.
15 A quenching bath should not be agitated so violently that foaming occurs on the bath surface. This means that air pockets are forming and that the maximum benefit of circulation is not being obtained.

The above are some of the more important considerations that apply in the design of work tanks. Many others could be mentioned.

Typical Work Tanks. Typical sketch layouts are given in Fig. 4 to 9. These are intended to show various types of work tanks, the quenching technique employed, the method of handling the parts treated and the application of agitation. Obviously, there can be many other combinations and variations not shown here.

Quenching Presses. One type of commercial quenching press is designed for holding and quenching gears and other parts so that they may be brought to the required hardness with minimum distortion. These presses and dies are designed and built to remove distortion that results from the heating cycle* and to apply the quenching medium in a controlled manner so that uniform quenching at the desired rate is obtained. This action is illustrated schematically in Fig. 10. The die contacts the heated part and the pressure of the press aligns the part mechanically as illustrated in Fig. 10*b*. This occurs before quenching starts and while the part is hot and plastic. The machine and dies then force the coolant into contact with the part in a controlled manner as illustrated in Fig. 10*c*. The quantity and rate of flow are controlled by the press. The distribution of the flow is controlled by the dies. The speed of the quench depends on the quenching medium and the amount of agitation. Exact control of the rate of cooling can be obtained by adjusting the rate of flow through the die.

The design of quenching dies is based on definite rules, and the basic equipments have been standardized to a considerable degree. Although basic types of dies are used on typical shapes, certain special parts must be made for each die in order to adapt it to the particular piece to be quenched. The manufacturers of the presses should be

* As an example of distortion during heating, consider the situation where one section of a part that is above or below the transformation temperature range is expanding with each increment of temperature rise at the same time that another section at the transformation temperature is contracting; in this manner serious upsetting can take place. Relief of residual stresses during heating can also cause distortion.

consulted in regard to die problems. One of the most important factors in all die design is that the piece to be quenched must have precise tolerances on those dimensions necessary for die contacts if optimum results are to be attained. The correlation of the areas of the part where the die is to make contact is equally important. For example, when quenching a gear, it is always desirable to "round up" the piece by die contact in the same bore that was used for chucking the part when the teeth were being cut. In a similar manner, die contacts on other types of parts are selected for their relation to the part as a whole and for their ability to bring the part to its original shape when suitable pressure is applied. All quenching dies are designed and built with provisions for adjusting the proportion of quenching flow through a given passage. Quenching to tolerances of 0.001 to 0.003 in. for round and flat is common practice when correctly designed dies are used on properly machined parts.

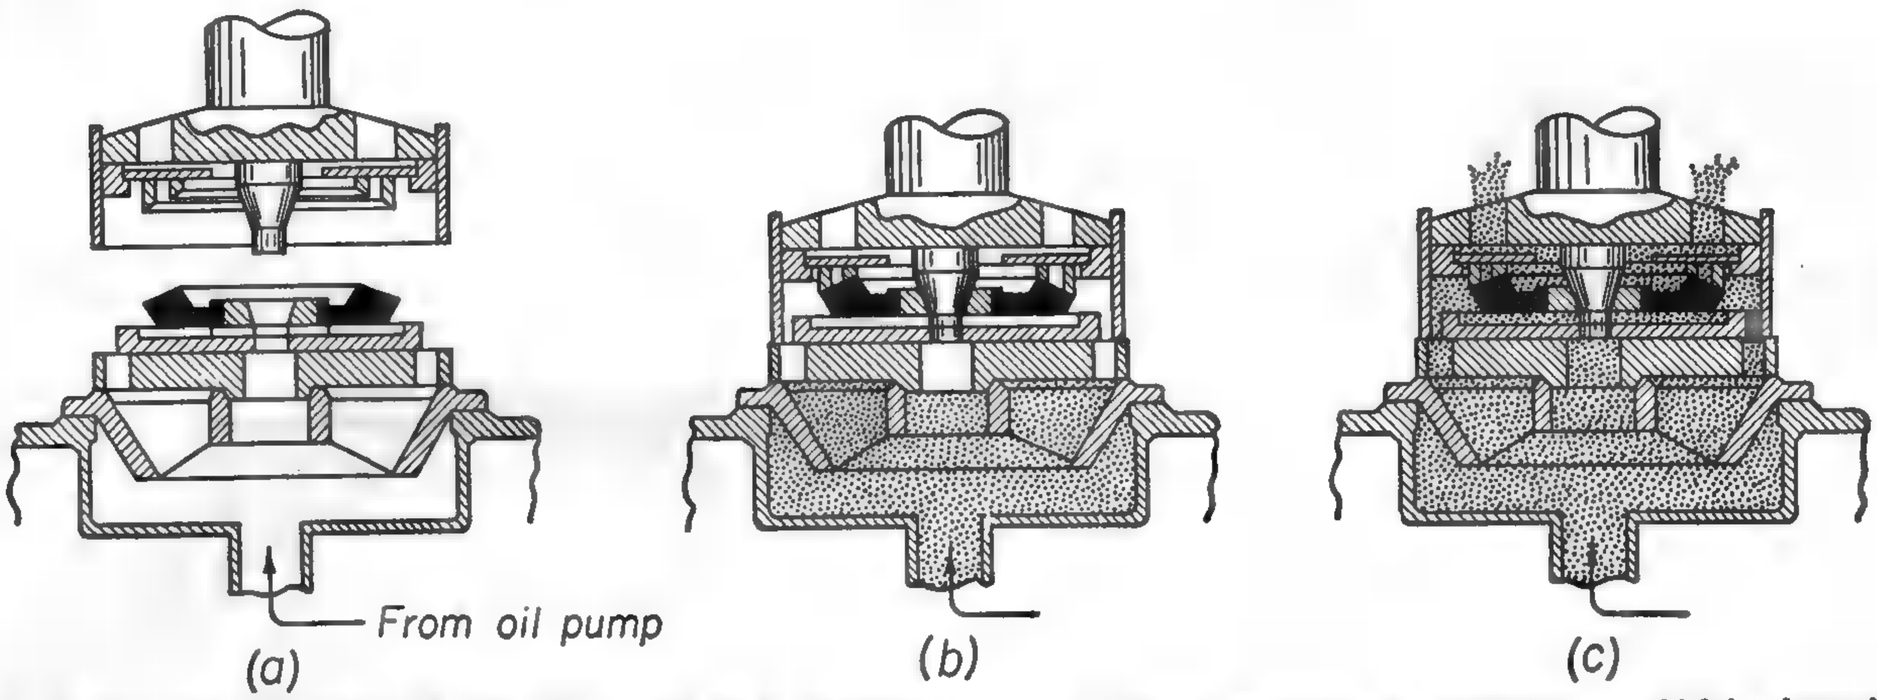

Fig. 10 (*a*) Quenching press with hot gear on the lower die in quenching position. (*b*) Upper die in contact with work piece, which has been aligned while still in the plastic condition. (*c*) Beginning of timing cycle; quenching oil forced into quenching chamber and around gear

The machines have a reservoir and recirculating pump system with valve and time controls so that at all stages of the quenching cycle, the volumes and rates of flow through the die are automatically changed to values preset to suit the requirements of the part. The built-in pumping system and reservoir reduce the external supply of quenching medium required, to approximately 35 gal per min while providing controlled flow through the die of as much as 225 or more gal per min, depending on the size of the machine. The external supply of quenching medium needed is determined by the heat absorption required and by the desired temperature rise of the medium. Because the die passages direct all the quenching fluid into close proximity to the piece, the supply from external sources need not be increased to allow for wastage and unutilized overflow.

In another commercial quenching press, the quench enclosure, the quenching dies and the work piece are rotated during quenching. This press is used to quench gears and other similar machined parts to meet required mechanical properties with a minimum of change in dimensions. With a given set of dies or tooling, this machine will mechanically re-align the hot and plastic work piece, in order to correct distortion caused previous to the actual quench, and will then automatically proceed with the quenching under controlled conditions. Quenching is facilitated by means of favorable die designs and the centrifugal action of the quenching fluid in the press.

This press will quench almost any machined part symmetrical to a common axis that fits the standard quench enclosure. Parts can be either quenched all over or, as with certain full-web, forged gears, a soft hub can be retained without masking off any portion of the work piece. The method of performing these operations, as illustrated in Fig. 11, is as follows:

1 Hot gear charged on lower die (Fig. 11*a*).
2 Pilot ram leads main ram to clamp hub to lower die. (Can also be used to center and expand arbor for ring gear tooling.)
3 Main ram closes to flatten rim of gear shown.
4 Quench enclosure, dies and gear rotate.
5 Quenching medium fills enclosure and approaches the hot gear that is clamped and corrected to dimensional change before quenching (Fig. 11*b*).
6 Quenching proceeds by pumping liquid into the chamber entering at the outside internal diameter. The liquid forms a dense cylinder with the inside "bore" decreasing rapidly until it reaches exhaust ports. In this instance the overflow pipes are set at a prescribed diameter to retain a soft hub. This feature is often desirable in full finishing the hub when the otherwise hardened gear is chucked from the "pitch line". Cool liquid at a definite temperature rapidly displaces hot liquid contacting the gear, so that controlled agitation removes heat from work surfaces for optimum quenching results (Fig. 11*c*). For work requiring "all-over" quench, the dies and exhaust ports are set up accordingly.
7 At the end of time cycle the upper die rises as rotation stops, and liquid flows out of the chamber.

These quenching presses incorporate design features to provide control over the following factors required in press quench operations:

a Adjustable pressures in both main and pilot rams.
b Variable and controlled volume of the flow of quenching fluid by use of built-in pumps that have a capacity of 250 gal per min.
c Full "all-over" quench or adjustable segmental quench to retain soft hubs.
d Adjustable controlled time of quench.
e Auxiliary reservoir built into machine to reduce demand on supply of quenching fluid.
f Controlled agitation that results in rapid quenching cycles.

Cold Die Quenching.[1] Heat treaters who have tried to avoid stresses caused in steel by nonuniform quenching, will naturally view rather skeptically any suggestion that these stresses may be employed to help straighten parts during heat treatment. However, this is essentially what happens when "cold die" quenching is used to harden certain steel parts. Use of the dies for quenching was originally developed for a particular job in which blades of an air-hardening steel were quenched and flattened between cold steel blocks. Cold dies that eliminated contact of liquid with the part, gave excellent results for flattening and hardening.

The process has been applied to other parts and it has developed into a useful tool for heat treaters. A hardening operation on a thin washer or disk, or on ■ long slender rod, has always been looked upon as the chief source of distortion; therefore, costly hand straightening and high losses in the form of scrap have been common on this class of material.

For example, large, thin thrust-washers, blanked out of cold rolled steel, which have oil grooves machined halfway through the thickness, always come from the blanking and machining operations considerably out of flat. A bow of 0.050 in. is quite common and even more may be found occasionally, but the washers after hardening are held flat within 0.005 in. The method used is an extremely simple one—the parts are squeezed between a pair of water-cooled die blocks, which replace the conventional quench.

The use of a die surface for a cooling medium is obviously limited to parts of large surface and small mass.

This might seem to be a severe limitation; however, it should be remembered that these parts give the worst trouble with warpage in hardening.

Coolers. *Thermal Cycle of Medium.* While quenching proceeds in a given system, heat is removed from the work piece and the temperature of the quenching medium obviously rises, unless otherwise cooled. Since uniform metallurgical results in the hardening operation depend on controlled conditions in the quenching process, coolers (and sometimes heaters) are necessary to maintain selected temperatures in quenching mediums.

Many types of heat exchangers are used in the cooling of quenching liquids and each offers certain advantages.

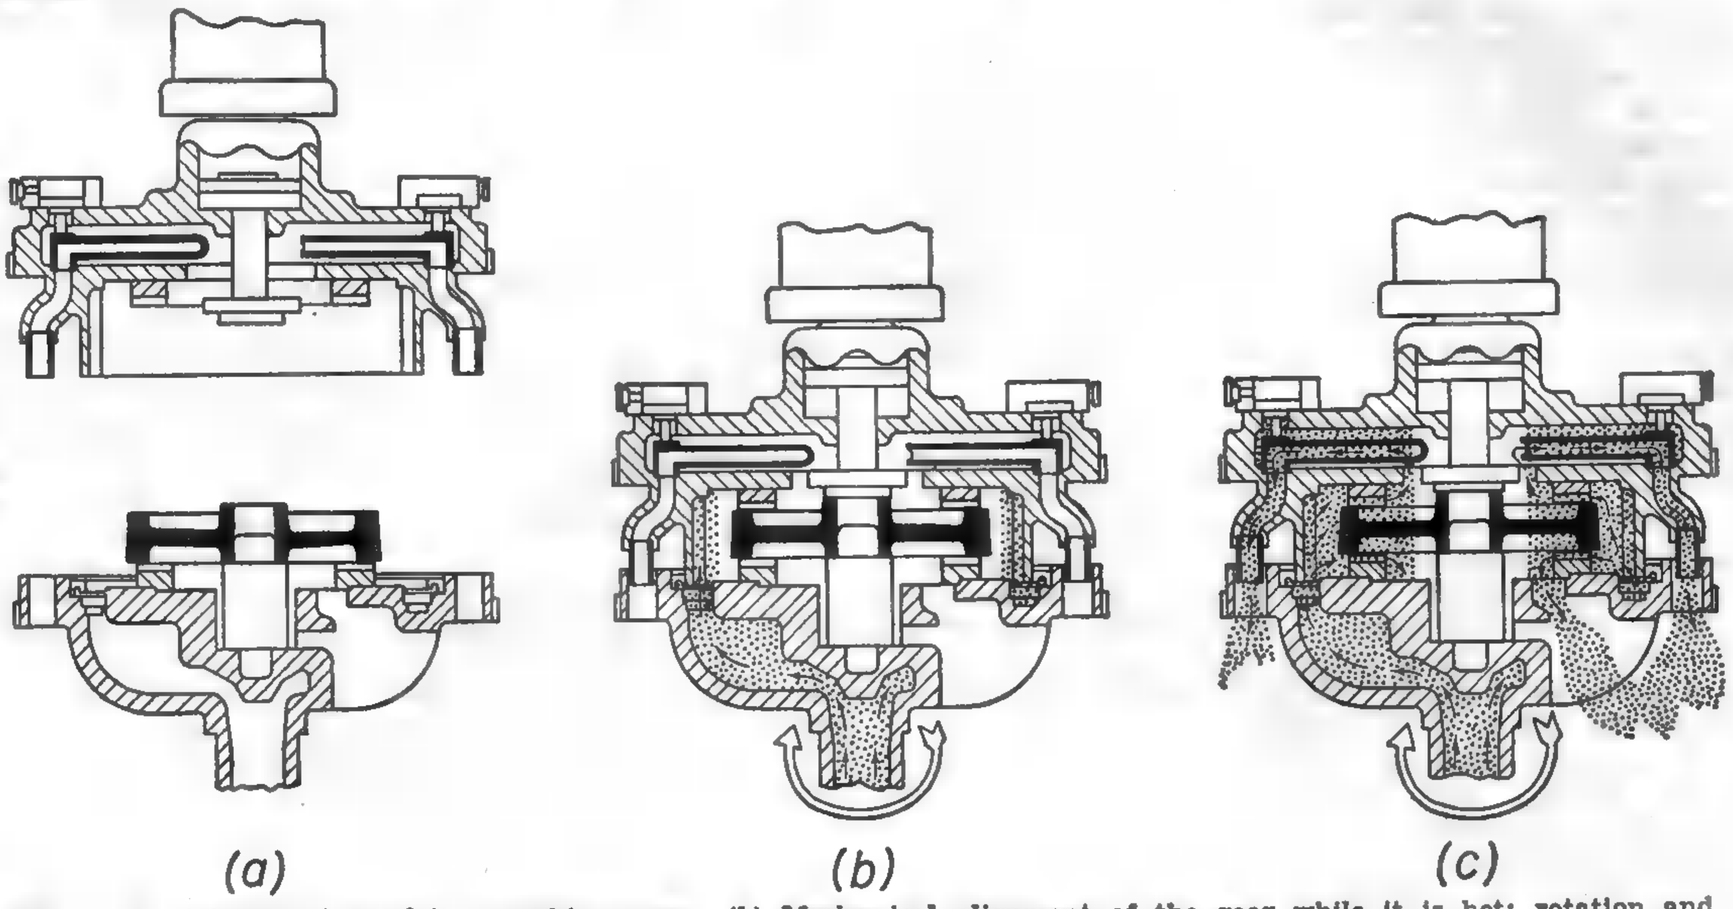

Fig. 11 (*a*) Hot gear charged in quenching press. (*b*) Mechanical alignment of the gear while it is hot; rotation and start of quench. (*c*) Continuation of centrifugal quench.

The rate of heat transfer through the unit always depends on the velocity of the liquids passing through the cooler; as the velocity increases, the rate of heat transfer increases. Therefore, if a unit is designed for high efficiency and suitable velocity of flow, the pumps that move the liquid are related to the cooler application.

Again, maintenance of cooling equipment is related to design. If a uniform temperature is held in the quenching oil, the problem of fouling is held to a minimum. Cooling equipment should always be designed for easy cleaning.

Shell-and-Tube Heat Exchangers. This type of oil cooler consists of a series of copper or steel tubes built into a steel shell. The quenching liquid is circulated through either the tube or the shell section, and the cooling liquid through the opposite section. City water is often used as the coolant, although with larger heat loads an evaporative water-cooling unit may provide the cooling water used in the heat exchanger. Well water is also used frequently. In general, city water is used when the total quenching load is less than 2000 lb per hr. However, the selection of the cooling medium depends on the cost of city water as compared with the operating and initial cost of the evaporative unit. In most instances the evaporative unit does not provide water at as low a temperature as can be expected from a well or the normal city source. Therefore, the heat exchanger is usually larger when the source of cooling water is an evaporative unit.

Maintenance of the shell-and-tube heat exchanger is negligible. A well-designed heat exchanger will provide for removal of the tubes for cleaning.

The shell-and-tube heat exchanger is flexible in its application and can easily be designed to meet all conditions, such as velocity requirements and the specifications regarding heat transfer.

Evaporative Coolers. This unit employs the evaporative principle of cooling. The unit consists of a pump or pumps used in recirculating water from a pan at the bottom of the unit through a series of nozzles near the top. A high-velocity fan circulates air over the spray water, thus lowering the temperature of the water. The cooled water is passed over the series of copper or steel tubes inside of which is circulated the quenching liquid that is being cooled.

If the cost of city water is high, this unit offers a definite operating economy. Maintenance of the fan and water-circulating pumps, and periodic cleaning of tubes are necessary.

Spray Towers. Spray towers, in general, are of three types: atmospheric, induced draft, and forced draft. The unit is usually installed outside the building and often on the roof. The water to be cooled is circulated from a pan or tank at the base, through the spray nozzle at the top of the tower. As the water is sprayed from the nozzle, it is cooled by evaporation caused either by normal movement of air or by mechanical circulation of air.

Such units are usually provided when the requirements for cooling water are great. Limitations, as in the evaporative cooler, are related generally to the local wet-bulb temperature. The unit may be installed to provide cooled water directly to the quenching tank or to furnish a cooling medium for the shell-and-tube heat exchanger.

Maintenance costs are, of course, related to the number of mechanical units involved. Pumps are necessary in all types for water circulation and, in some types, motor-driven fans, used for air circulation, are another maintenance factor.

General. In addition to the three popular types of cooling equipment listed, direct refrigeration has been used, as well as combinations of the three types described above. Local conditions of cost, temperature, pressure and availability have a direct bearing on the selection of equipment for cooling the quenching medium.

The quenching mediums used and the allowable range of metallurgical results in the as-quenched steel have a direct influence on types of coolers to use. For example, if water quenching is used on rough carbon steel forgings, more often than not, no coolers are used. The inlet of cold water under thermostatic control will maintain satisfactory temperatures in the work tank as the excess fluid overflows to a sewer or to a well for reclaiming.

In caustic or brine quenching, often a closed recirculation system is used in conjunction with a storage tank only. The volume in the circuit, balanced against the increase in temperature of the quenching medium, is such that acceptable temperatures are maintained in the medium without coolers, for a given hardening operation.

However, for the oil quenching of full-finished gears or axles, elaborate heat-exchanger and cooler equipment is installed under accurate thermostatic control. Such sys-

tems usually employ heaters in order to control further the complete temperature cycle of the oil.

Selection. To select a cooler properly in the quenching circuit, the maximum demand or heat load must be determined from the following known data:

1 Weight of steel quenched during a specified period
2 Specific heat of steel
3 Temperature of steel entering the quench
4 Temperature of steel leaving the quench
5 Temperature of quenching liquid entering the work tank
6 Temperature of quenching liquid leaving the work tank
7 Characteristics of the quenching medium, such as: (*a*) specific heat, (*b*) specific gravity, (*c*) viscosity, flash point, boiling point and (*d*) point of vaporization, for some toxic solutions.

From the above data and with full knowledge of costs and acceptable metallurgical results, proper cooling equipment can be selected for the quenching system.

Oil Heaters. Often it is necessary to increase the temperature of the quenching liquid after a week-end or overnight period of shutdown. The actual increase in temperature may not be great but in some instances the large volume involved results in a considerable heating load. By the use of automatic time-control equipment, it is possible to allow four or five hours for complete heating of the liquid in the system, and thus the heat exchanger is not necessarily large.

If a shell-and-tube heat exchanger is used in the system for cooling, it can also be employed for heating. It is necessary, however, that steam or hot water be available as a heating medium. The heating cycle can be made fully automatic by the installation of temperature-control valves.

Electric heating elements are often used to increase the temperature of quenching liquid, but the cost of power is often prohibitive if the heating load is of any consequence.

Supply Tanks. In general, storage tanks are necessary for two reasons: (1) If large batches are quenched, it is necessary to provide sufficient quenching liquid in storage to satisfy the cooling demand set up during the quench. If this storage is not available, it is necessary, of course, that the cooling equipment be large enough to handle the heat transfer based on the load per minute during the batch quench. (2) Space is also provided for storing the quenching liquid, in order to allow for draining the other units in the system for cleaning and maintenance.

Whenever possible, the storage tanks should be installed so that all other equipment will drain to them. This will simplify the operation of the system and will eliminate the need for additional return pumps, which are difficult to balance. Since the storage tank will become a point of settlement for all sediment in the system, a manhole should be included in the tank to allow for entrance in cleaning. If a foot valve is to be installed in the tank, a removable suction tube is advantageous. This tube is constructed in such a way that both the tube and the foot valve can be removed from outside the tank.

Pumps. Pumps are installed primarily for one or both of two purposes: (1) It is necessary to maintain a specified flow of the quenching liquid through the heat exchanger. This is usually a continuous flow and need be only enough to compensate for the heat transfer. (2) Agitation is necessary in the quenching tank and quite often a second pump is installed for this purpose.

Centrifugal pumps are used wherever possible, since wearing is minimized and usually the initial cost is lower. However, where a storage tank is employed, it is usually necessary to raise the oil from the storage tank to the quenching tank.

Since a centrifugal pump is not self-priming, it is customary to install a small positive-displacement pump for priming the centrifugal pump when necessary. Since a continuous-duty pump is usually small, this is often a positive-displacement pump and is used both for continuous circulation when necessary and also for priming the centrifugal pump used in agitation.

By the installation of valves, it is usually feasible to connect the pump in such a way that it can be used for emptying or filling the quenching tank or tanks. Valves should also be installed to simplify the repair of pumps. Valves should always be installed on both sides of the pump so that it is not necessary to empty any of the tanks or piping when repairs are made.

Centrifugal pumps are not designed for great suction-lift operation and therefore should be installed as near the oil supply as possible. Consideration should also be given to the resistance to flow set up by the piping system so that the pump itself may be properly sized. If resistance of the piping is considerably less than anticipated, the motor of the pump is likely to overload.

Mechanical Conditioning. In addition to the coolers that control the temperature of the quenching medium, other equipments are necessary in the installation to condition the medium mechanically.

Strainers are necessary in order to protect the pumps from dirt and scale picked up in the quenching medium. They are very important in oil systems and should be of large size and designed so as to provide free flow and accumulation of scale without clogging. Strainers should be installed in pairs, suitably valved off so that one can be cleaned while the other is operating.

Sometimes for precise oil-quenching operations, a filtering system is installed to remove trapped air from the oil, as well as free carbon and water.

Hazard Protection. Special consideration should be given to quenching systems that use brine or caustic solution. During quenching, fumes are released that should be drawn off into hoods by a proper ventilating system.

When oil is used, the question of fire hazard is important and particularly when large unit loads are handled in the work tank. There are several fire-extinguishing systems, but the most effective types use carbon dioxide (CO_2) as the agent.

Carbon dioxide extinguishes fire rapidly because it reduces the concentration of oxygen to a point at which burning cannot occur. It does not contaminate the quenching oil or cause damage to steel in process, and it leaves no residue to be cleaned up.

Two types of carbon dioxide fire-extinguishing systems are in general use—high pressure and low pressure. In high-pressure systems the liquid CO_2 is stored in steel cylinders that may be manifolded together. In low-pressure systems liquid CO_2 is stored in a single refrigerated, insulated pressure vessel at approximately 0 F, and at corresponding relatively low pressure of 300 psi. In either type of system, actual protection of quenching operations may be provided as part of a larger system covering additional hazards, or the quenching tank system may be complete in itself.

In low-pressure systems, increased cooling capacity is added to the other fire-extinguishing properties of carbon dioxide, since liquid CO_2 stored at 0 F yields 47% of CO_2 "snow" (finely divided particles of "dry ice") when released, as contrasted with a yield of 24% at 80 F. The cooling capacity of CO_2 is in large measure related to the amount of CO_2 snow in the discharge. Control of temperature of the stored liquid also provides uniform characteristics in regard to discharge and extinguishing. Low-pressure CO_2 systems have capacities from 500 lb to scores of tons of CO_2.

A typical low-pressure CO_2 fire-extinguishing system for the protection of an average continuous quenching tank and its associated oil pit would utilize a one-ton storage unit. Two thermostats over the quenching tank and three in the pit would provide complete automatic operation. In addition, a pushbutton timer station enables the system to be put into its automatic sequence of operation if fire is observed before the thermostats have been actuated. The electrically operated valves are supplemented with pilot valves for manual operation of the system in the event of failure of electrical power.

Linear nozzles running the full length of the tank on two sides, discharge across the surface of the oil. Three orifice-type nozzles release CO_2 into the pit in order to extinguish immediately any fire that may have spread from the quenching tank. Further protection is given the machinery controlling the conveyer and oil circulation by means of a special type of nozzle. For this given typical system the entire discharge period for all nozzles is 40 sec, during which approximately 600 lb of CO_2 is released.

Thermal Formulas and Basic Calculations. In designing any quenching system for the heat treatment of steel, certain basic formulas are used in calculations that determine

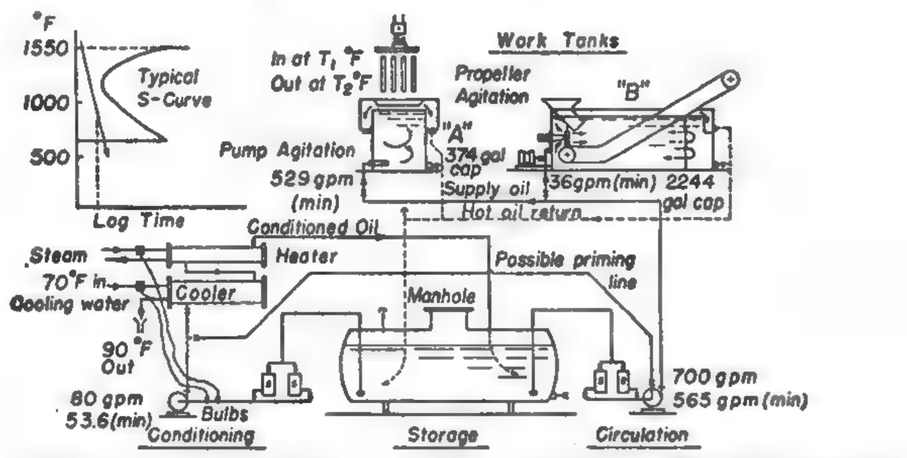
the minimum theoretical requirements. The following symbols are used in the sample calculations given below:

W = Weight of steel, pounds quenched per hour
S_s = Mean specific heat of steel
T^1 = Temperature of steel entering bath, deg Fahr
T_2 = Temperature of steel leaving bath, deg Fahr
H = Btu removed per hour (maximum heat load)
W_m = Weight of quenching medium, pounds
S_m = Specific heat of quenching medium
T_3 = Initial temperature of quenching medium before quench, deg Fahr
T_4 = Final temperature of quenching medium after quench, deg Fahr
R = Temperature increase in medium during quench, deg Fahr
V_m = Volume of medium, gallons, in the system

The following sample calculations are based on a given system, shown in Fig. 12. The known factors are:

S_s = Mean specific heat of steel = 0.17
W_a = 500-lb batch quench, once each hour in Tank *A*
W_b = 1000-lb continuous quench in Tank *B*, evenly distributed through the hour
T_1 = 1550 F steel entering both tanks
T_2 = 150 F steel leaving both tanks
Medium = Oil, 7.5 lb per gal, 0.5 specific heat or S_m
T_3 = 120 F, design temperature of oil entering work tanks
T_4 = 150 F, temperature of oil leaving work tanks
Well water at 70 F available for cooling
374 gal = Volume of Tank *A*
2244 gal = Volume of Tank *B*

NOTE: Based on S-curves, hardenability characteristics and section of parts quenched, it can be estimated that heat will be removed from steel quenched in Tank *A* in 2 min. Generally it may be assumed that the average work piece will lose heat to oil at a rate of 1 min per in. of thickness at the smallest cross section.



Known Factors
W = 500 lb for "A" Mass Load
W = 1000 lb for "B" Continuous Load
S_s = 0.17
T_1 = 1550 F
T_2 = 150 F
Oil Medium, 7.5 lb per gal; sp ht, 0.5
T_3 = 120 F
T_4 = 150 F

Determined Factors
Circulation pump 700 gal per min
Vm = 1058 gal, "A"; 2116 gal, "B"; Total, 3174 gal (min)
Storage = 374 + 2244 = 2618 (min) + 50% = 4000 gal
H = 119,000 Btu per hr avg, "A"
238,000 Btu per hr avg, "B"
357,000 Btu per hr avg, Total
Cooling water rate = 36.7 gal per min
Conditioning pump rate = 80 gal per min

Fig. 12 Quenching system for which the various factors are calculated in the text

Tank A

The heat load for Tank A:

$H = W_a S_s (T_1 - T_2) = 500 \times 0.17 \quad (1550 - 150) = \quad 119{,}000$ Btu per hr

Since this load must be absorbed by the quenching oil in approximately 2 min, enough oil must be provided to allow no more than $T_3 - T_4$ or 30° rise. Therefore, the volume of quenching oil required in the system is:

$$V_m = \frac{H}{W_m S_m (T_4 - T_3)} = \frac{119{,}000}{7.5 \times 0.5 \quad (150 - 120)} = 1058 \text{ gal}$$

To determine the rate of flow through the cooling equipment for Tank *A*:

$$\frac{1058}{60 \text{ min}} = 17.6 \text{ gal per min}$$

To determine rate of flow to Tank *A* to absorb heat as specified:

$$\frac{1058 \text{ gal to absorb heat}}{2 \text{ min (period of heat transfer)}} = 529 \text{ gal per min}$$

Tank B

The heat load for Tank *B*:

$H = WS_s (T_1 - T_2) = 1000 \times 0.17 \quad (1550 - 150) = 238{,}000$ Btu per hr

This heat load is evenly distributed through the cooling system during the hour, and therefore the cooling requirements are as follows:

$$V_m = \frac{H}{W_m S_m (T_4 - T_3)} = \frac{238{,}000}{7.5 \times 0.5 \quad (150 - 120)} = 2116 \text{ gal or } 36 \text{ gpm}$$

Theoretically, the volume of oil in the system need not be held at a minimum in continuous quenching, since the cooling equipment is designed to remove the heat from the quenching oil at the rate at which it absorbs heat from the steel being quenched. However, for purposes of design, a certain volume is desirable as noted.

Referring to Fig. 12, a circulation pump of 529 gpm is required for agitation in Tank *A* and 36 gpm to displace oil in Tank *B* so that 2116 gph can return to storage. This total of 529 plus 36 or 565 gpm, plus a safety factor of 25%, calls for an installed capacity of 700 gpm.

In Tank *B*, quenching is continuous and a motor-driven agitator is indicated. Here the problem is to maintain the velocity of quenching oil that passes over the continuously falling steel as it is discharged from the chute to the quench conveyer. For the small pieces considered, a 5-hp motor is provided for the agitator and it can be assumed that the velocity of oil will be satisfactory to assure required cooling rates to the steel quenched.

Referring to the storage tanks in Fig. 12, to clean either or both work tanks, 374 + 2244 = 2618 gal must be provided.

Practical design would call for 50% increase for a total storage capacity of 4000 gal. If oil is purchased in tank car lots, obviously the storage must be increased accordingly.

With 70 F cooling water, 90 F outlet, the cooling water rate for coolers is:

H = 119,000 Btu per hr for Tank *A*
H = 238,000 Btu per hr for Tank *B*
357,000 Btu per hr total

$$\text{Flow through cooler} = \frac{357{,}000}{8.33 \times 20° \text{ rise} \times 60 \text{ min}} = 36.7 \text{ gpm}$$

Circulation of medium from storage through the cooler for conditioning must be at the rate noted above; 17.6 gpm for Tank *A* plus 36 gpm for Tank *B*, or 53.6 gpm. For practical design, an 80-gpm pump would be installed to circulate oil through the cooler.

This pump will usually be a positive-displacement pump, operating continuously. In any heat-exchanger equipment, increasing the velocity increases the rate of heat transfer; therefore, this pump capacity may increase or decrease according to recommendations of the manufacturer of the cooler. The pressure drop through cooler and heater should be such as not to overload the motor of the heat-exchanger pump.

Because this is a positive-displacement or gear-type pump, the sketch shows it hooked up to prime the centrifugal large-volume pump supplying oil to the tanks.

In almost every instance, experience indicates that a quenching system designed to handle a heavier load than intended will be more satisfactory than a system designed to the minimum requirements. For instance, an oil system overdesigned will lower ventilating requirements, will tend to eliminate fire hazard, and will maintain quenching oil in improved condition for longer usage, since sludging will be reduced and the only loss will be drag-out.

Gas Quenching.[2] "Gas quenching" is the term applied to the rapid cooling of heated metals in a high-velocity stream of a gaseous medium. If the gas is of suitable composition, the original surface of the work remains bright and free from any surface decarburization during this heat treatment.

The cooling rates secured by bright gas quenching are intermediate between those obtained by liquid quenching and by normalizing (Fig. 13). Normalizing is the slowest form of gas quenching since the cooling is carried out in still air at ordinary temperature.

An example of gas quenching may be drawn from the heat treatment of X4130 steel aircraft tubing. In large production furnaces, the cooling rates for normalizing are too slow for obtaining desired properties in this material. The necessary rates of cooling must be considerably faster

and can be secured only by forced cooling in a continuous stream of cold gases so arranged that the gases being heated by contact with the hot steel are constantly replaced by a fresh supply of cold gases that strike the work at high velocity for maximum rates of heat transfer.

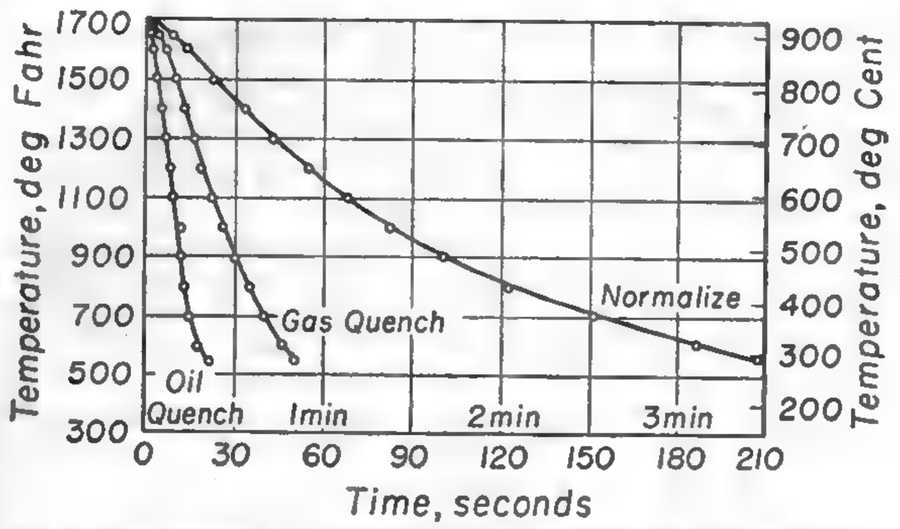


Fig. 13 Comparison of cooling rates obtained by gas quenching, oil quenching and normalizing (cooling in still air)

Gas Quenching Apparatus. This result is readily accomplished by use of a gas quenching zone (*see* reference 2). It is located immediately adjacent to the discharge end of the heating zone. As the tubes leave the heating chamber, they are blasted from both top and bottom by large volumes of cold gases issuing from a series of nozzles. Having absorbed heat from the hot steel, the gases are withdrawn from the cooling chamber through a number of outlet openings provided on both sides of the chamber. The gases are then flowed over four water-cooled coils by means of two large recirculating fans that deliver the cooled gases back to the gas nozzles for discharge at high velocity. The gas recirculating system is gastight and consists of two separate units, one of which is placed above the work material and the other one below the work material. Suitable dampers are provided for control of the volume of recirculated gas.

Rate of Gas Quenching. The gas quenching zone of a 4-ft effective width is capable of bright gas quenching at a continuous rate 4500 to 5000 lb per hr of X4130 welded aircraft tubing, from 1650 F to black heat in less than 1 min. The actual quenching time depends on the rate of recirculation of gas and on the speed of the conveyer, which in turn is governed by the size and wall thickness of the tube. In a continuous furnace of the above hourly capacity, tubes having a wall thickness of 0.049 in. were gas quenched from 1650 F to black heat in 30 sec.

tion of austenite will then occur at constant subcritical temperature or during later cooling, depending on the time-temperature combination employed in the heat treatment. Martempering, austempering and modifications of these processes involve interrupted quenching.

The cooling rates of the outside and center of pieces that have similar size and shape, quenched in water, oil, air and salt, and the process of transformation by these various quenching methods are illustrated in Fig. 14. In each process that is depicted, the quenching speed exceeds the critical cooling rate.

The greater the quenching speed, the greater the temperature difference between the surface and center of the work piece. With a very rapid quench, such as shown by the curve representing water quenching in Fig. 14, there

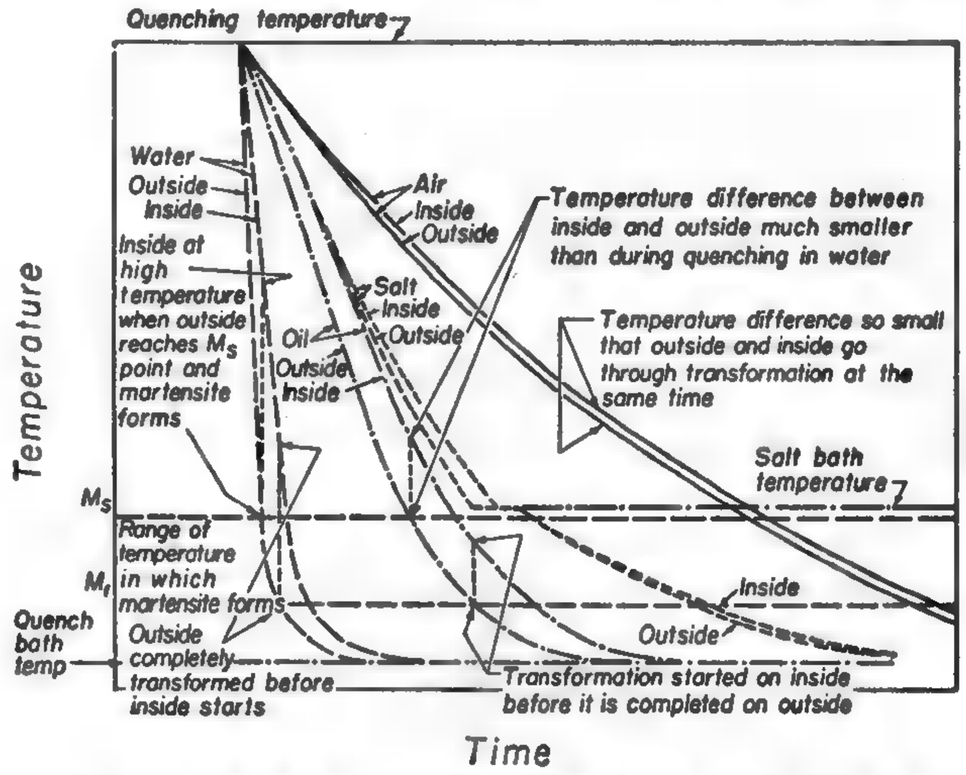

Fig. 14 Cooling curves for the surface and center of a steel cylinder quenched in water, oil, hot salt and air

is a rather large temperature difference between the outside and center of the part. Transformation of austenite to martensite progresses during cooling through the martensite transformation range and, for the conditions of Fig. 14, the outside is completely transformed before the austenite in the center of the piece has cooled to the M_s temperature. Thus a large volume of unstable austenite is entrapped in a case of hard, brittle martensite. Later, as the center cools through the transformation range, the entrapped austenite transforms to martensite, with an increase in volume. This nonuniform expansion causes excessive residual stresses that result in distortion and sometimes in cracking.

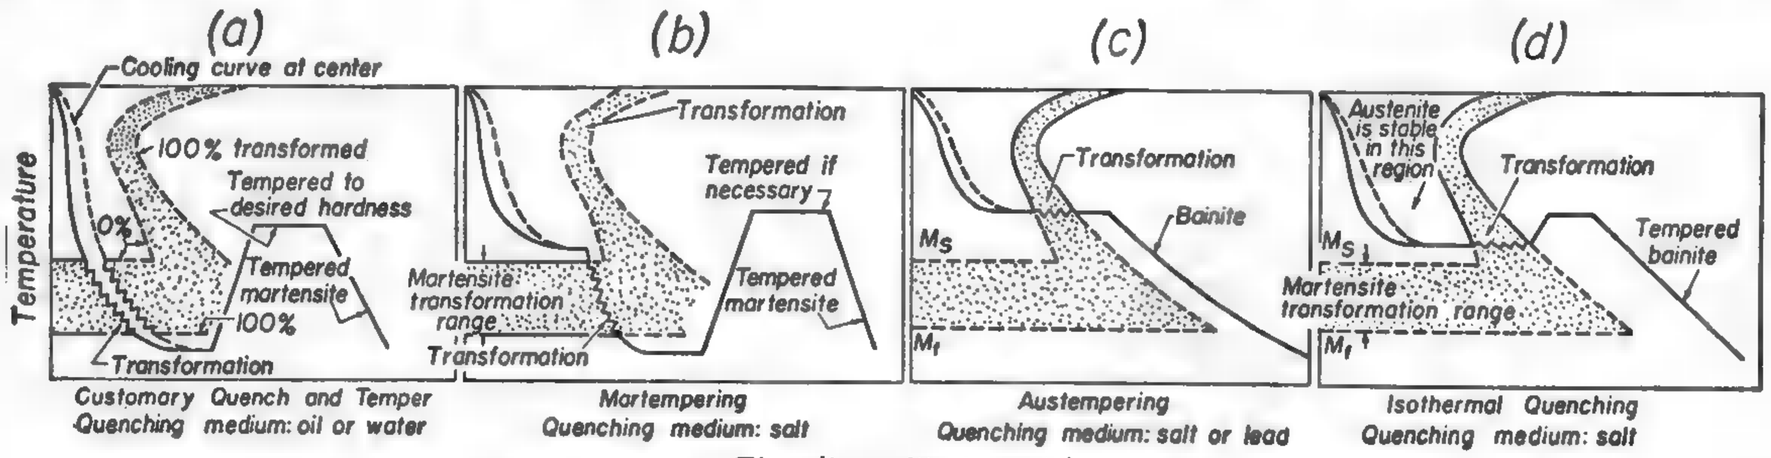

Fig. 15 Diagram of four important quenching methods

Cooling Medium. The gaseous quenching medium normally employed is the bright-annealing gas that is produced by the partial combustion of a fuel gas. It consists of approximately 5% CO_2, 10% CO, 12% H_2, 1% H_2O, and 72% N_2. This gas provides a faster rate of cooling than air, because of its higher heat capacity and because of the avoidance of scale on the surface of the work. Since the gas quenching zone is of gastight construction, any of the other commercial gas atmospheres may readily be applied.

The Interrupted Quench.[3, 4, 5] The interrupted quench is a controlled method of heat removal in which cooling is stopped at some temperature above or just within the martensite transformation range of the steel. Transforma-

The curves that indicate oil quenching show a slower rate of cooling and a smaller temperature difference between the outside and the center of the piece. This results in a greater amount of martensite formation in the center before the surface reaches the M_f point.

Steels that harden during air cooling are used for complicated dies and sections because the center and surface transform to martensite at virtually the same time, thus minimizing the possibility of quenching cracks.

Martempering. This process (Fig. 15*b*) involves quenching from the austenitizing temperature into a molten bath at a temperature near the M_s point of the steel, and holding in the bath long enough for the center and outside to equalize in temperature; then cooling further at a moderate rate, usually in air, so as not to allow any great difference in temperature between the outside and center (Fig. 15*b*). Formation of martensite then occurs fairly uniformly throughout the piece during cooling to room temperature, avoiding excessive residual stress.

The temperature of the quenching bath should be near the M_s point; if the temperature is much below M_s, an appreciable quantity of martensite will form and may defeat the purpose of the treatment. A temperature of 400 F is satisfactory for the martempering of many steels containing about 0.40% C. As discussed elsewhere in this Handbook (page 611) the M_s temperature varies with carbon and alloy content and this influences the choice of temperatures for the quenching bath.

Austempering. This process (Fig. 15*c*) consists of transferring the austenitized steel rapidly to a hot liquid quenching bath held at constant temperature below the transformation range, usually at from 450 to 800 F, for a sufficient time to allow transformation to a nonmartensitic structure. The steel is then cooled to room temperature by any convenient means, usually water quenching.

Another form of the interrupted quench is a modification of the austempering method (Fig. 15*d*). This method is a three-step process: heating to austenitize; quenching in an agitated heated salt at 400 F or higher and holding at this temperature to permit isothermal transformation; then immersing in a third bath at a higher temperature in order to temper the isothermal product. In this way advantage may be taken of the greater cooling rate of the liquid salt at a lower temperature and larger pieces may be successfully quenched and austempered.

The cooling rates, measured at 1000 F, obtained during quenching a ½-in. steel sphere from 1475 F in oil at room temperature and in salt at 400 and at 500 F are:

Mineral oil at 70 F	100 to 145 °F per sec
Molten salt at 400 F	115 °F per sec
Molten salt at 500 F	95 °F per sec

Agitating the molten salt at 400 F will bring the cooling power of the bath up to the equal of that of still mineral oil at room temperature. Stated in another way, the quenching speed of agitated salt at 400 F has an H-value (*see* page 495) of 0.25 to 0.30 on parts that have a machined surface. The quenching value is somewhat lower for materials having a light scale.

Salt mixtures that melt at about 300 F and may be used as high as 1100 F are most often employed in interrupted quenching. A compounded oil that has a high flash point has been used satisfactorily in martempering.

Quenching from Surface Heating. Surface heating by flame or induction produces in a relatively short time a more or less steep thermal gradient that results in loss of heat to the cold core. This loss of heat varies from a mild effect to a drastic heat transfer, which, in some induction or oxyacetylene-heated jobs, obviates an external quench.

Surface hardening nearly always produces high stresses because of the rapid heating and cooling, and local heating and transformation. The danger of cracking, particularly of surface checking, is usually present and must be guarded against with careful quenching practice. In general, drastic quenches are required, particularly since carbon steels are usually employed.

Quenching from surface heating is carried out in a number of ways, made possible by the flexibility of the heating processes. However, they may all be grouped under two general types: immersion quenching, and pressure-spray quenching.

The simpler of these is immersion quenching. This consists of placing the part in a tank of quenching medium, either automatically or manually with tongs. A modification of immersion quenching is the use of a submerged inductor, where the part is heated while immersed in the quenching medium. This requires considerable power per unit area, and is generally done with radio frequency; the advantages are instantaneous quenching and a profound effect on heating pattern where odd shapes are involved.

The great majority of parts to be surface hardened are pressure-spray quenched. Spray quenching methods may be classified as area or continuous. The area method consists in heating an area and then applying a spray quench, usually with a "quench ring", a shaped fixture containing a channel for quenching medium and small holes through which the liquid is applied to the heated area. Continuous spray quenching involves passing the work pieces through the heating zone into a quenching spray at such a rate that the proper cooling rate is obtained. Either work piece or treating equipment may be moved.

Pressure water-spray quenching may result in cracking. Cooling rates are extremely high and care must be taken not to use a more drastic quench than is necessary. For uniformity it is advisable that the pressure and temperature of the quenching water be controlled. For this purpose a circulating system is often used, which frequently supplies both quenching water and any necessary cooling of the equipment, such as for an induction generator or flame head. When the system is used for cooling equipment, hardness of the water must be investigated and treating equipment provided if necessary, since hard water would clog the cooling passages. Water used for both cooling and quenching is generally held at 90 to 105 F. An important precaution in surface hardening is to provide adequate quenching area. A quench that does not reach all the heated portion may cause serious cracking.

Occasionally oil is used in a pressure-spray quench, particularly with induction heating. Oil temperature is generally in the neighborhood of 80 to 100 F, and here again temperature and pressure must be controlled. Oil pressures as high as 100 psi or more are used, and with these higher pressures, cooling rates at the surface approach those of a conventional water quench. In one application seven-pitch plain carbon steel gears (C1045) are being pressure-oil quenched to the maximum hardness available for steel of that carbon content.

The Influence of Mass in the Heat Treatment of Steel

By E. J. Janitzky*

It is well known that the properties of quenched steel depend on the mass of the piece that is being quenched as well as on the chemical composition of the steel. For example, if a series of cylinders of SAE 1045 steel with different diameters are quenched from the same temperature by the same procedure in the same quenching medium, the mechanical properties of the quenched cylinders will vary in a regular manner depending on the diameters of the cylinders. The difference will also be evident, although different in magnitude, after the usual tempering operation. The difference in mechanical properties results from the rate of decomposition of austenite. Alloying elements such as nickel, chromium and manganese increase the hardenability in the same size and shape of piece; that is, they make the steel deep hardening by decreasing the rate of decomposition of austenite.

The hardness depends not only on the diameter of the section that is heat treated but also on the depth at which the hardness is measured within the piece; that

* Metallurgical Engineer, Chicago

is, if the section is large enough so that it has not hardened completely to the center. This would also be true of properties such as tensile strength, yield point, elongation and reduction of area, if they were to be determined at different depths within the piece. Characteristic hardenability curves are shown in Fig. 1, in which the Rockwell C hardness of water-quenched cylinders of various diameters is plotted against diameter of the section. Fig. 1 shows a plain carbon steel, SAE 1045, at the left, and a deeply hardening alloy steel, SAE 6140, at the right. In cylinders ½ in. in diam the SAE 6140 hardens completely and in those 1 in. in diam almost completely.

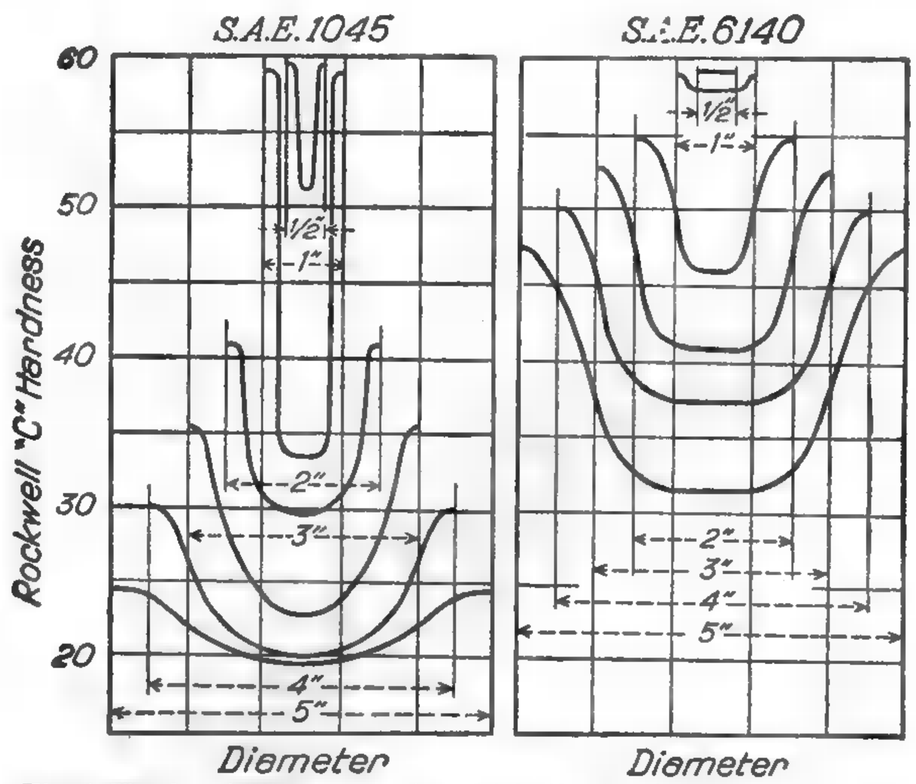

Fig. 1 Hardenability curves in which the Rockwell hardness is plotted against the diameter of the sections (Grossmann).

In cylinders ½ and 1 in. in diam of SAE 1045, about the same surface hardness is obtained as in the SAE 6140, but the hardness decreases much more rapidly toward the center of the piece. Even in cylinders ½ in. in diam, the SAE 1045 is not hardened completely. In sections 2 in. in diam, and larger, the surface hardness as well as the hardness in the interior of the piece is less in SAE 1045 steel than in SAE 6140. In sizes that harden completely there is little change in hardness with size. As soon as a size is reached that fails to harden completely, the difference between the surface and center hardness first increases as the size of the section is increased and, after reaching a maximum, decreases again as the mass becomes so great that the steel is virtually inert to heat treatment.

Tensile strength and elastic limit will decrease with increase in the diameter of the section; elongation and reduction of area will increase. In bars smaller in diameter than one that will just harden completely, there is relatively little change in mechanical properties with size in commercial quenching operations. In the sizes that fall somewhat short of complete hardening, the change in mechanical properties with size is relatively rapid, but the change becomes less marked as the size is increased, until the mass becomes so great that the steel is virtually inert to heat treatment. Alloying with chromium, nickel, or manganese counteracts this inertness, while combinations of chromium, nickel, or manganese with vanadium, molybdenum, or tungsten may or may not have deep hardening potentialities, depending on the composition, grain size and heating temperature.

If a series of cylinders of SAE 1045 and a similar series of cylinders of an alloy steel, such as SAE 2340, are quenched under identical conditions, a series of mechanical properties changing with increasing size will be obtained for each steel. However, the mechanical properties of the SAE 2340 series will be different for identical diameter from the SAE 1045 series because of the presence of nickel in the SAE 2340 steel. A similar effect will be obtained by the use of any of the alloying elements mentioned above, although the amount of the change in hardenability will depend on the particular element and its percentage in the steel, together with the carbon content of the steel. These alloying elements not only affect the hardenability in quenching but also cause the steel to resist tempering more than do plain carbon steels.

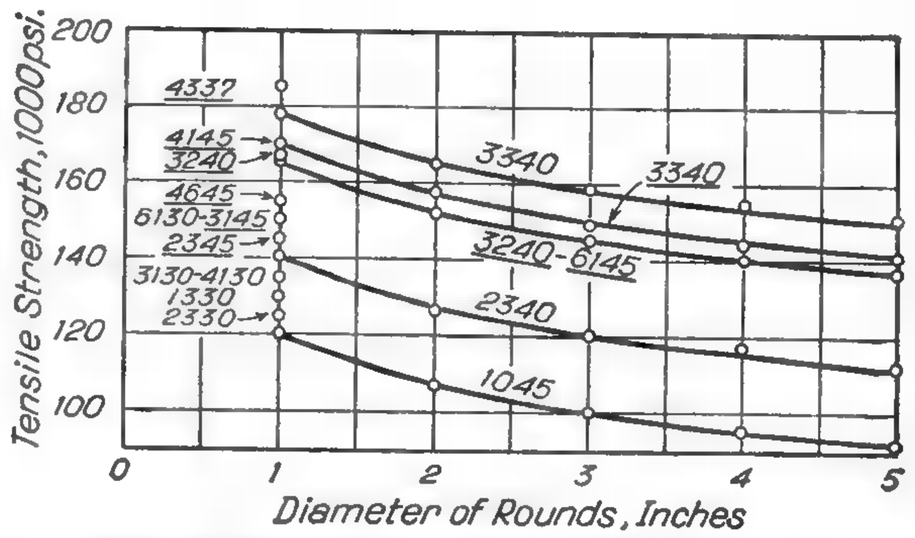

Fig. 2 Relationship between tensile strength and diameter of section for several steels. Normalized, quenched, tempered at 1000 F.

The relationship between tensile strength and diameter of section for SAE 1045 and several common alloy steels, is shown in Fig. 2. These steels were normalized, then quenched from appropriate temperatures in oil or water, as indicated, and tempered at 1000 F. The oil-quenched specimens are underscored in Fig. 2. The specimens for the tension tests were taken from midway between center and surface of the quenched and tempered cylinders, except for those 1 in. in diam, in which the specimens were taken from the center. It is evident that the loss in tensile strength in each steel bears a regular relationship to the increase in diameter of the section. The following relationship was observed: As the diameter of the section increases in arithmetic progression, the tensile strength decreases in hyperbolic order according to the following equation:

$$P_2 = P_1\left(\frac{d_1}{d_2}\right)^n$$

in which P_1 = the tensile strength corresponding to the diameter d_1
P_2 = the tensile strength corresponding to the diameter d_2 and
n = an exponent (different for each curve).

The Heat Treatment of Carbon Steels

By M. L. Frey* and R. W. Roush*

THIS article covers the heat treatment for wrought carbon steels of all the types generally used except those classified as tool steels. The more common applications are discussed, with the exception of case hardening, spring making and the hardening of metal-cutting tools and dies. Treatments and applications that are not included here may be found in other sections.

Chemical Composition. The chemical compositions of the steels given here are according to the SAE and AISI specifications for carbon steels on page 307.

Temperature and Quenching Medium. Table I gives the commonly used temperatures and quenching mediums for heat treating these steels. The only steels listed in the table are those necessary to illustrate the carbon range to which a particular treatment applies. Similar steels of approximately the same carbon content will require the same treatment. For a discussion of the principles involved, the reader is referred to the articles "Heat Treatment of Metals" and "Principles of the Heat Treatment of Iron and Steel" in this Handbook.

To simplify consideration of the treatments for various applications, the steels will be classified as follows: Group I, 1010 to 1025; Group II, 1030 to 1050; Group III, 1055 to 1095.

Group I, Steels 1010 to 1025. The three principal types of heat treatment used on these low-carbon steels are: (1) process treating of material to prepare it for subsequent operations; (2) treating of finished parts to improve mechanical properties; and (3) case hardening, which is covered elsewhere in this Handbook.

Table I. Heat Treatments for Carbon Steels

Steel No.	Normalize, deg Fahr	Anneal, deg Fahr	Quench	
			Temp, deg Fahr	Medium
1010	1650 to 1750	1000 to 1350[a]	1650 to 1700	Water[c]
1015	1650 to 1750	1000 to 1350[a]	1650 to 1700	
1020	1650 to 1750	1000 to 1350[a]	1600 to 1675	Oil[d, e]
1025	1600 to 1700	.....	1600 to 1675	
1030	1600 to 1675	1250 to 1375[b]	1575 to 1650	Water[c]
1035	1575 to 1650	1575 to 1650[b]	1525 to 1600	Water[c]-Oil
1040	1575 to 1650	1550 to 1625[b]	1500 to 1575	Water[c]-Oil
1045	1550 to 1650	1525 to 1600	1475 to 1550	Water[c]-Oil
1050	1550 to 1650	1525 to 1600	1475 to 1550	Water[c]-Oil
1055	1525 to 1625	1500 to 1575	1450 to 1550	Water[c]-Oil
1060	1525 to 1625	1500 to 1575	1450 to 1550	Water[c]-Oil
1064	1525 to 1625	1500 to 1575	1450 to 1550	Water[c]-Oil
1070	1525 to 1625	1500 to 1575	1450 to 1550	Water[c]-Oil
1080	1525 to 1625		1450 to 1550	Water[c]-Oil
1085	1525 to 1625	1500 to 1575[b]	1450 to 1550	Water[c]-Oil
1095	1525 to 1625		1450 to 1550	Water[c]-Oil

(a) For explanation of this temperature range, see discussion of Group I.
(b) For spheroidizing, anneal at 1250 to 1375 F.
(c) Brine or caustic is frequently used. See text.
(d) Soluble oil solution is used for hardening bolts.
(e) Mineral oil is used when quenching for machinability.

The process treatment of these steels is applied principally to sheet and strip at the mills, to prepare it for forming and drawing. These treatments have been specialized to a very high degree; the details depend on the intended application of the material and the available equipment. The temperatures used are near the lower transformation temperature, and are somewhat higher for hot finished than for cold finished material. The time cycles and cooling rates vary widely. Detailed discussion is beyond the scope of this article.

It is often necessary to process anneal drawn products between operations, thus relieving work strains in order to permit further working. This operation is normally carried out at temperatures between the recrystallization temperature and the lower transformation temperature. The effect is to soften by recrystallization and grain growth of ferrite. It is desirable to keep the recrystallized grain size relatively fine; for that reason rapid heating and short holding time at temperature are used. The low temperatures also reduce scaling. The customary practice is to discharge the parts from the annealing temperature into air; thereafter it is usually necessary to remove scale. If surface protection is desired, the material should be heated in liquid baths or in furnaces having a controlled atmosphere.

A similar practice may be used in the treatment of low-carbon cold headed bolts made from cold drawn wire. Sometimes the strains introduced by cold working so weaken the heads that they break through the most severely worked portion under slight additional strain. Process annealing, as described previously, is used to overcome this condition. Since the temperatures used are close to the lower transformation temperature, this treatment results in considerable reduction of the normal mechanical properties of the shank of the cold headed bolt. A more suitable treatment is stress relieving at about 1000 F, in order to retain much of the strength acquired in cold working and to provide ample toughness. A common practice is to combine a stress-relieving treatment with a quench from the upper transformation temperature or slightly above, producing mechanical properties that approach those of the cold drawn stock. A common quenching medium is a water solution of soluble oil, the use of which produces two desirable results: (1) the surface of the parts acquires a pleasing black color accepted as a commercial finish, and (2) the speed of the quench is slowed to the point where fully quenched hardness is not produced, so it is not necessary to temper the parts.

Heat treatments are frequently employed to improve machinability. The generally poor machinability of the low-carbon steels, except those containing sulfur or other special alloying elements, results principally from the fact that the proportion of free ferrite to carbide is high. This situation cannot be changed fundamentally, but the machinability can be improved by putting the carbide in its most voluminous form, pearlite, and dispersing fine particles of this pearlite evenly throughout the ferrite mass. Normalizing is commonly used with success, but best results are obtained by quenching the steel in oil from 1500 to 1600 F. With the exception of steel 1025, no martensite is formed and the parts do not require tempering.

Group II, Steels 1030 to 1050. Because of the higher carbon content, quenching and tempering become of increasing importance when steels of this group are considered. They are the most versatile of the carbon steels, because their hardenability (that is, their response to quenching) can be varied over a wide range by suitable control. This important subject is discussed on pages 489 to 502.

It should be pointed out that in this group of steels there is a continuous change from water-hardening to oil-hardening types; as a result, the hardenability is very sensitive to changes in chemical composition, particularly to the content of manganese, silicon and residual elements, and to grain size. In addition, these steels are very sensitive to changes in section. In evaluating the results of heat treatment, careful consideration must be given to the effect of prior structure and to surface condition at the time of quenching.

The rate of heating parts for quenching has a marked effect on hardenability under certain conditions. If the structure is nonuniform, as a result of severe banding or lack of proper normalizing or annealing, extremely rapid heating, such as may be obtained in liquid baths, will not allow sufficient time for diffusion of carbon and other alloying elements in the austenite. As a result, nonuniform or low hardness will be produced unless the duration of heating is extended. In heating the steels that contain free carbide (for example, spheroidized material) sufficient time must be allowed for the solution of the carbides; otherwise the austenite at the time of quenching will have a lower carbon content than is represented by the chemical composition of the material, and disappointing results may be obtained. This condition may be produced deliberately; see Group III, below, for an example.

These medium-carbon steels should be either normalized

* Allis-Chalmers Manufacturing Company, Milwaukee
• Timken-Detroit Axle Company, Detroit

or annealed before hardening, in order to obtain the best mechanical properties after hardening and tempering. Parts made from bar stock are frequently given no treatment prior to hardening, but it is common practice to normalize or anneal forgings.

Although these steels do not possess the machinability of screw stock, they machine reasonably well. Most bar stock, both hot finished and cold finished, is machined as received, except in the higher carbon grades and small sizes that require annealing to reduce the as-received hardness. Forgings are usually normalized, since this treatment avoids the extreme softening and consequent reduction of machinability that result from annealing. In some instances a "cycle treatment" is used. In this practice the parts are heated as for normalizing, and are then cooled rapidly in the furnace to a temperature somewhat above the nose of the S-curve; that is, within the transformation range that produces pearlite. Then the parts are held at temperature or cooled slowly until the desired amount of transformation has taken place; thereafter they are cooled in any convenient manner. Specially arranged furnaces are usually required. Details of the treatments vary widely and are frequently determined by the furnace equipment available.

Cold headed products are commonly made from these steels, especially from the ones containing less than 0.40% C. Process treating before cold working is usually necessary because the higher carbon decreases the workability. For certain uses, these steels are normalized or annealed above the upper transformation temperature, but more frequently a spheroidizing treatment is used. The degree of spheroidization required depends on the application. After the mechanical operations are finished, the parts are heat treated by quenching and tempering.

These medium-carbon steels are widely used for machinery parts for moderate duty. When such parts are to be machined after heat treatment, the maximum hardness is usually held to 320 Brinell, and is frequently much lower.

The following list gives the range within which the hardness of representative parts is usually found.

Part	Grade of Steel	Hardness Number
Crankshafts	1040 to 1045	228 to 286
Connecting rods	1040 to 1045	187 to 241
Wheel flanges	1035 to 1040	302 to 444
Steering arms	1035 to 1040	207 to 269
Shafts	1045 to 1050	228 to 402
Couplings	1030 to 1045	207 to 321
Thrust washers	1040 to 1045	341 to 514
Wheel lugs	1040 to 1045	364 to 477

The selection of a quenching medium will vary with the steel composition, the design of the part, the hardenability of the steel and the hardness desired in the finished part. When the design of the part permits, the best combination of strength and toughness results from full hardening (martensitization) of the part, followed by suitable tempering. For these steels, this procedure nearly always means quenching in water, brine or caustic soda, except for parts of light or complicated section. The lower carbon steels, if fine-grained and abnormal, are shallow hardening even when quenched in caustic; while the higher carbon steels, when coarse-grained and normal, will give hardnesses of 450 Brinell when small sections are quenched in oil and will exhibit satisfactory hardening in pieces as large as 1 in. in diam.

Water is the quenching medium most commonly used because it is best known and is usually cheapest and easiest to install. Caustic soda solution (5 to 10% NaOH by wt) is used in many instances with improved results. Compared with water, it is a faster and, therefore, a more thorough and more uniform quench, producing better mechanical properties in all but light sections. Because of its rapid action, more scale is removed from the parts. When used hot (130 to 160 F), caustic soda solution frequently makes possible drastic quenching of parts that could not be water quenched without breakage. The disadvantages of caustic soda are that it can be used only in a closed system in which provisions are made for cooling; operators must be protected against contact with it; the solution must be checked constantly and the proper strength maintained; and wool clothing disintegrates rapidly after contact with it. Cotton clothing is not affected.

Salt solutions (brine) are often successfully used. Up to 100 F they produce almost as good results as caustic, but are much less effective when hot. Therefore, they cannot be used when breakage is a problem, combined with the necessity for a drastic quench. Like caustic, they require a closed system. Salt solutions are not dangerous to operators but their corrosive action on iron or steel parts of equipment is very serious.

When the section is light or the properties required after heat treatment are not very high, oil quenching is often used. This nearly always eliminates the breakage problem and is very effective in reducing distortion.

The wide range shown in the quenching temperatures in Table I is made necessary by the fact that a wide range of conditions must be met. It is not intended that such a temperature range should be used on any one part or under any given set of conditions. General practice is to use suitable temperatures plus or minus 10°F. The lower temperatures should be used for the higher manganese steels, light sections, coarse-grained material and water quenching; higher temperatures are required for lower manganese, heavy sections, fine grain and oil quenching.

A type of treatment finding considerable use is the light case hardening of many machinery parts. The material is heated to its normal hardening temperature in an activated bath or in a suitable atmosphere and is then quenched. This treatment produces a thin, hard skin for wear resistance. Only low-temperature tempering can be done on such parts; otherwise the surface hardness will be impaired. It is necessary to choose the degree of hardenability in relation to section size so as to obtain the required degree of toughness in the product tempered at a low temperature. In using such parts, it must be borne in mind that the presence of the hard skin reduces notch toughness below that which would be found if the skin were absent.

From these steels are made many common hand tools, such as pliers, open-end wrenches, screw drivers, and a few edged tools—for example, tin snips and brush knives. The cutting tools are necessarily quenched locally on the cutting edges, in water, brine or caustic, and are subsequently given suitable tempering treatments. In some instances the edge is suitably time quenched; then the remainder of the tool is oil quenched for partial strengthening. When made of these grades of steel, pliers, wrenches and screw drivers are usually quenched in water either locally or completely and are then suitably tempered.

Group III, Steels 1055 to 1095. Steels of this group are used chiefly for heavy machinery parts, hand tools, agricultural cutting tools, and springs. The subject "Heat Treatment of Springs" is discussed on page 644.

Forged parts should be annealed for these reasons: (1) because refinement of the forging structure is important in producing a high-quality hardened product, and (2) because the parts come from the hammer too hard for cold trimming of the flash or for any machining operations. Ordinary annealing practice, followed by furnace cooling to 1100 F, is satisfactory for most parts as given in the table.

Most of the parts made from steels in this group are hardened by conventional quenching. However, special technique is necessary at times; a few examples are described. Both oil and water quenching are used—water, for heavy sections of the lower carbon steels and for cutting edges; oil, for general use. Austempering and martempering (*see* page 629) are often successfully applied to parts made of steels in this group. The principal advantages from such treatments are considerably reduced distortion, elimination of breakage, in many instances, and greater toughness at high hardness.

For heavy machinery parts, such as shafts, collars and the like, steels 1055 and 1061 may be used, either as-normalized and tempered for low strengths or as-quenched and tempered for moderate strengths. Other steels in the list may be used, but the combination of carbon and manganese in the two mentioned makes them particularly well adapted for such applications. It must be remembered that even with all hardenability factors favorable, including the

use of a drastic quench, these steels are essentially shallow hardening as compared with alloy steels, because carbon alone, or in combination with manganese in the amounts involved here, does not promote deep hardening to any great extent. Therefore, the sections for which such steels are suited will be definitely limited. In spite of this limitation the danger of breakage is real and must be carefully guarded against when such parts are being treated, especially when changes in section are involved.

Hand tools made from steels in this group include open-end wrenches, Stillson wrenches, hammers, mauls, pliers and screw drivers; and cutting tools, such as hatchets, axes, mower knives and band knives. The combination of carbon and manganese in the steels used may vary widely for the same type of tool, depending partly on the equipment available for manufacture and partly on personal experience with or preference for certain combinations. A manganese content lower than listed will be used in some tools. This is justified when it makes a particular carbon range easier to handle, but it should be understood that for many applications, a combination of lower carbon and higher manganese would serve just as well. Hand cutting tools, discussed later, are an exception.

For hardening wrenches (except the Stillson type), screw drivers, pliers and similar tools, oil quenching is generally used, followed by tempering to the required hardness range. Even when no reduction of as-quenched hardness is desired, stress-relieving at 300 to 375 F is desirable, to reduce residual strain and so help prevent sudden service failures. In Stillson-type wrenches the jaw teeth are really cutting edges and are nearly always quenched in water or brine to produce a hardness of 50 to 60 Rockwell C. Either the jaws may be locally heated and quenched or the parts may be heated all over and the jaws locally time-quenched in water or brine. The entire part is then quenched in oil for partial hardening of the remainder. In this way considerable structural strength is obtained.

Hammers must possess high hardness on the striking face and somewhat lower hardness on claws. They are usually locally hardened and tempered on each end, depending on their type. The striking face is always quenched in water or brine. Satisfactory service depends on getting the proper depth of fully hardened (martensitic) surface on this face, and following with stress relieving at about 350 F. Final hardness on the striking face is usually Rockwell C 50 to 58; on claws, 40 to 47.

Hand cutting tools, particularly axes and hatchets, must possess high hardness and high relative toughness in their cutting edge, as well as the ability to hold a keen edge. Since nothing is so effective as carbon in imparting the latter property, the carbon content is always higher than if hardness and toughness alone were to be considered. Many such tools are given an ordinary furnace anneal following forging, but high-quality tools are prepared for hardening by spheroidization, which may be performed as a separate operation following regular annealing. Most frequently, however, the refining and spheroidizing treatments are accomplished by quenching in oil from 1600 F, and then tempering at 1250 to 1375 F. The quench keeps the carbide in a finely divided state and from this condition spheroidization takes place rapidly at the temperatures specified.

For hardening, the cutting edges of such tools are usually heated in liquid baths to the lowest temperature at which the piece can be hardened, and are then quenched in brine. The quick heating of the liquid bath plus the low temperature fail to put all the spheroidal carbon into solution. As a result the cutting edge of the tool consists of martensite containing less carbon than indicated by the chemical composition of the steel and containing many embedded particles of cementite. In this condition the tool is at its maximum toughness, relative to its hardness, and the embedded carbides promote long life of the cutting edge. Final hardness is 55 to 60 R_c.

Manufacturers of agricultural implements make much use of the steels in this group. Braces, control rods, shafts and similar parts are often made of high-carbon steels, untreated in order to obtain increased strength at low cost. The principal heat treated parts are plowshares, moldboards, coulters, cultivator shovels, disks for harrows and plows, mower and binder knives, ledger plates and band knives. Those parts used for cutting or turning soil must be moderately tough and must have the ability to resist abrasion. They are made with various combinations of carbon and manganese that will permit full hardening.

Plowshares and cultivator shovels are usually quenched in water or brine to obtain 500 to 600 Brinell. Plowshares, moldboards and cultivator shovels are often made from "soft center steel", which consists of a layer of dead soft material between two equally thick layers of high-carbon steel. This material is rolled from specially cast composite ingots. Such parts are heat treated to produce high hardness in the outer layer, leaving the relatively soft interior layer to provide toughness. The final product is similar in physical properties to a case hardened part; in fact, these parts are sometimes case hardened.

The grass-cutting and grain-cutting tools are usually made of 1090 or 1095, because of the effect of carbon in providing the desired edge that will last long in service. These parts are made from strip stock by blanking, and no annealing is done, except probably some process annealing performed in the rolling mills, at or below the transformation range. Spheroidization is, therefore, only occasionally obtained. Local hardening is done either by induction heating or in continuous furnaces provided with fixtures that permit the pieces to be heated on the cutting edges only. Upon discharge, the parts are quenched all over in oil and are tempered at a low temperature. Final hardness on the cutting edges is in the neighborhood of 55 to 60 Rockwell C.

The Heat Treatment of Steel Castings

By the Subcommittee on Heat Treatment of Steel Castings*

THIS article applies generally to commercial castings for ordinary construction purposes and not for special uses. Where authoritative specifications exist (for example, ASTM specifications), the practice listed conforms to such specifications.

Chemical Composition.

Carbon Steels	C	Percentage Mn max	Si max	P max	S max
Low-carbon steels	less than 0.20	1.00	0.60	0.05	0.05
Medium-carbon steels	0.20 to 0.50	1.00	0.60	0.05	0.05
High-carbon steels	more than 0.50	1.00	0.60	0.05	0.05

* The members of this subcommittee are R. A. Gezelius. *Chairman* (General Steel Castings Corporation), John Juppenlatz (Lebanon Steel Foundry) and David Zuege (Sivyer Steel Casting Company).

Alloy Steels. Only the so-called "low-alloy" steels are considered in this section. The actual compositions involved are too numerous to list here. Typical steels and the properties obtainable are listed in Table I. These steels contain a maximum of 0.60% C and additions of one to four alloying elements. However, the total alloy content is usually less than 5%.

Specific data concerning hardenability and transformation are unavailable for certain cast steels. In these instances the information on wrought steels can be used. The cast steels will usually possess slightly higher hardenability than wrought steels of a comparable composition because of the higher manganese and silicon content of cast steels. These variations, as well as those in the "S-curves", are minor in nature and should cause no difficulty in the heat treatment of commercial castings.

Preliminary Care After Casting. After being poured, the castings should be allowed to cool in the molds to a temperature below the transformation range. When they have cooled to room temperature, they will have a coarse "as-cast" structure. While the castings are in this condition, residual stresses from uneven cooling may be sufficient to cause rupture in the higher carbon and alloy steels during handling. Therefore, when the hardness is high or the castings are of such design as to be conducive to high residual stresses, a preliminary stress relieving or an annealing treatment may be required to obviate breakage in handling. These treatments, described below, should be started before the casting has cooled to less than 500 F.

Table I. Typical Compositions and Mechanical Properties of Cast Steels

For local heating of castings with high hardenability, any treatment such as burning, cutting and welding should be performed only on castings preheated to minimize the danger of excessive air hardening, which often results in cracks. This preheating for welding and for similar operations requires higher temperatures and greater care as the hardenability increases. Temperatures of 200 to 300 F are sufficient for the low-carbon steels; as high as 700 to 800 F may be required for high-carbon alloy steels.

Equipment for Heat Treatment. For best results in heat treating operations, controlled furnaces are required so that uniform temperatures and heating rates can be maintained. When air or liquid quenching is involved, the quenching equipment is important if rates of cooling are to be controlled. *See* the articles on pages 615 to 629.

Full Annealing. The castings are heated above the transformation temperature range at a rate that will obtain a reasonable degree of uniformity of temperature within each casting. A rate of 150 to 200°F per hr is usually satisfactory for this purpose. The casting should be held at temperature long enough for the very large crystals formed during freezing to be broken up by recrystallization, and for a more homogeneous material to be produced by the diffusion of elements from regions of microsegregation formed during solidification.

Recrystallization is completed as soon as the temperature rises above the transformation range. Within this range the rate of diffusion is rather slow but it increases rapidly with increasing temperature; consequently temperatures approximately 200°F higher than the transformation temperature range are usually employed.

Very small carbon steel castings can be homogenized in a comparatively short time; for larger carbon steel castings experience has indicated that 1 hr per in. of maximum section is satisfactory. This rule may be modified for extremely heavy sections, since 10 to 12 hr at temperature is usually the maximum time required.

After soaking at the proper temperature for the required length of time, the castings are permitted to cool slowly in the furnace to a temperature of 1000 F or less; then the rate of cooling may be accelerated.

Full annealing ordinarily produces good ductility values accompanied by tensile and yield strengths lower than those produced by the other methods of heat treatment. Impact values are also usually low. A coarse grain structure results when high annealing temperatures are employed. Usually only carbon steels are fully annealed.

Normalizing. In this treatment the castings are heated above the transformation temperature range and are held at that temperature for the proper length of time, in the same manner as for full annealing. Thereafter they are removed from the furnace and permitted to cool in still air.

Although normalizing is not a drastic hardening process, variations in the rates of cooling through the transformation range will influence the resulting mechanical properties. A 1-in. section will cool faster and yield higher strengths than a 2-in. section cooled under similar conditions. Therefore, because of these variations in cooling rates, lower strengths and hardnesses may be expected within the heavier sections of a casting that contains both light and heavy sections. Also, in batch-type furnaces the cooling rate is normally retarded in the central portion of the load, so the method of furnace loading must be considered carefully if uniform results are to be obtained.

Cooling in an air blast is not considered normalizing, since this treatment produces cooling rates more like those employed in conventional quenching operations.

Homogenizing. The castings are heated uniformly, as in annealing or normalizing, to some temperature well above the upper transformation range for at least 1 hr per in. of maximum thickness, and are then cooled from that temperature, usually in still air.

Homogenizing is important only for higher alloy steels prior to quenching operations for hardening. It is usually not required for carbon or low-alloy steels produced to meet ordinary commercial specifications. Quenching temperatures are usually too low to promote effectively a complete diffusion of carbon, particularly in alloy steels, and to break up the as-cast structure. These homogenizing temperatures range usually from 1750 F to considerably more than 2000 F, with time at temperature decreasing as the temperature increases. Air-cooling from these temperatures seems to be beneficial in preventing reversion of segregates found after cooling in the furnace.

Liquid Quenching. This treatment is required when mechanical properties are desired that cannot be produced by annealing, normalizing, or normalizing and tempering.

The castings are heated above the transformation temperature range, are held above that range for a proper period of time, and are then cooled rapidly in a liquid bath to a temperature lower than that associated with the maximum rate of austenite transformation.

Both heating and quenching equipment should be accurately controlled for uniformity of results. Water or oil may be used, depending on the rate of cooling required.

The holding temperatures for quenching are usually about 100 F above the transformation range. The time at temperature is 30 min to 1 hr or more per in. of maximum cross section, depending on the sluggishness of the alloy used and the time required for carbides to go into solution.

When the castings have been properly and uniformly heated, prompt transfer to a suitable quenching tank is essential. Quenching tanks should be of sufficient size, or the quenching medium should be sufficiently cool, to prevent a rise in temperature of more than 20 F in the quenching medium during the quenching operation. Adequate circulation is needed to obtain uniform cooling rates. Castings that are treated simultaneously must be arranged in the furnace and on the quenching racks in such a way that the hot furnace gases and the quenching medium may circulate freely.

Quenching should be continued until the temperature of the entire casting is lower than 500 F, or until a temperature is reached within the martensite range, thus hindering the formation of intermediate transformation products that might be undesirable.

Proper quenching may be hampered by the presence of various thicknesses within one casting. Since the heavier sections cool more slowly than the lighter sections, a liquid quenching treatment may not be suitable for some castings. This uneven cooling may cause cracking in the lighter sections; however, methods are available to minimize the danger. Some of the methods that may be used are differential quenching, spray quenching, "mudding up" lighter sections, or protecting them with plates to prevent excessively rapid cooling.

Tempering. This treatment, which follows normalizing or hardening operations, removes stresses set up in castings during nonuniform cooling. Tempering also increases ductility and impact resistance and decreases the tensile and yield strengths of the hardened material.

The castings are heated uniformly to the proper tempering temperature, are held at temperature for approximately 1 hr per in. of section (minimum usually ½ hr) and are then cooled. The temperatures employed may range from 400 to 1275 F, depending on the hardness and other mechanical properties desired. It is considered good practice to increase the time at temperature from the usual 1 hr per in. of effective cross section when temperatures of less than 850 F are employed, in order to insure the complete removal of residual stresses.

Temperatures higher than 1275 F are rarely employed, since austenite may form and hardening may be encountered in certain types of alloy steels. Obviously, low temperatures are employed for maximum hardness and high temperatures for maximum ductility. When tempering quenched castings, it is important to permit the casting to cool to a temperature low enough to complete the martensite transformation before reheating. This temperature may be as low as 250 F, depending on the composition of the alloy involved. However, it is important that castings of high hardness be tempered promptly after quenching, in order to relieve stresses and obviate cracking.

It is a common practice to cool castings in the furnace from the tempering temperature to some intermediate temperature between tempering and room temperature, and then to cool further in still air. Cooling in still air from the tempering temperature or even quenching in water from the tempering temperature is desirable when temper brittleness may be encountered and when good impact resistance is required at low temperatures.

Stress Relieving. If the relief of stresses is the only consideration, temperatures lower than 500 F are of little value and temperatures higher than 1000 F are usually not required. Experimental work has indicated that a temperature of 750 F will reduce stresses approximately 50% and that temperatures of 1000 F will reduce stresses more than 90%.

Tempering quenched steels at temperatures as low as 350 to 450 F will relieve excessive stresses and induce little or no softening or loss in strength. However, tempering temperatures lower than 700 F are seldom used in the treatment of commercial steel castings; in fact, temperatures higher than 900 F are usually employed. Increased temperatures for tempering will cause a progressive loss in strength, along with progressive improvement in ductility and impact resistance.

In normalized steels, temperatures lower than 1000 F will have little effect on strength or ductility.

Time-Temperature Quenching. When the size and design are such that quenching might cause cracking if the castings were kept in the water or oil until cold, the castings may be removed from the quenching bath when the heaviest section has cooled to about 500 F. The temperature should then be permitted to equalize in the various sections by conduction. For complete martensite formation, higher alloy steels may require additional cooling in still air, but low-alloy steel and carbon steel will usually be properly hardened when quenched to 500 F and will then be ready for tempering.

To ascertain the time required for quenching, in order to produce the desired temperature in heavier sections, thermocouples or temperature sticks (Tempil) may be used on pilot castings or test specimens of similar thickness.

Delayed Quenching (Subcritical). When the alloy content is sufficient, the castings may be heated and held at a temperature above the transformation temperature

range, then cooled in air in such a manner that no part of the casting reaches a temperature lower than 1000 F. The temperature of the castings may then be equalized at 1000 F in a furnace, and the steel may be quenched to about 300 F. This treatment serves to reduce the stresses, since the temperature differentials are less than those obtained during quenches from higher temperatures and the danger of cracking is thus greatly reduced.

Quenching in Heated Baths. Martempering may be accomplished by quenching castings in liquid baths at 300 to 800 F. The effectiveness of this heat treatment is governed by the composition and by the S-curve involved. In martempering, the rate of cooling in the quenching bath is highly important. The time in the quenching bath determines the mechanical properties obtained. Many small castings are now being treated by this method without subsequent tempering.

Case Hardening. The several methods of case hardening described on pages 677 to 702, are applied to steel castings in the same manner as to wrought steels.

The Heat Treatment of Heavy Forgings

BY THE SUBCOMMITTEE ON LARGE FORGINGS*

HEAVY FORGINGS comprise masses that weigh substantially more than those encountered in the usual large-volume, repetitive heat treating operations employed in the production of parts for automobiles, trucks and tractors, and in other practice involving similar sections. The class may be considered to include parts from approximately four inches in thickness or diameter to the largest dimensions forged.

The heat treatment of heavy forgings may consist of annealing, normalizing, quenching and tempering, or various combinations of these treatments to produce the mechanical and metallurgical properties required in a given part. The treatment of heavy sections is subject to a number of controlling factors that are more important than with smaller sections of steel. Many of these factors vary with the size of section and are further affected by shape, chemical composition, and the desired mechanical properties. The procedure that is followed in the heat treatment of heavy forgings will be determined to a large extent by experience in handling each specific part. The mechanical and metallurgical properties that can be obtained are affected by the mass, which limits the rate of heating and increases the period required for holding at soaking temperature. Likewise, the mass reduces the possible rate of cooling. Consequently the possibility of obtaining fully martensitic structures may be remote, even when the sections involved have been quenched. Therefore the normal expectancy is lower values for mechanical properties with increased size of section, a fact that is recognized in nearly all specifications for heat treated forgings. In many instances multiple treatments are required in developing high, uniform values for any composition, especially when the steel has been heated repeatedly during the forging operation.

Furnaces. Furnaces for heating heavy sections are necessarily large, yet they must be capable of heating uniformly and yielding to varying time-temperature cycles within prescribed temperature variation. Oil, gas and electricity are satisfactory sources of heat, provided the above requirements can be met.

Heating. In treating heavy forgings it is good practice to avoid charging a cool forging into a hot furnace. Ordinarily a furnace temperature is recommended that does not exceed 300 to 500 F for alloy steel and 300 to 800 F for carbon steel. After being placed in the furnace, the forging should be permitted to equalize at furnace temperature before heat is applied. When forgings have been transported hot from the forge to treatment shops, they should be allowed to transform in the proper temperature range under controlled conditions in the furnace—a precaution that tends to prevent flakes and thermal cracks—before reheating for subsequent treating operations. The rate of heating should be uniform and is governed by the size and shape of the part being heated. Too rapid heating of heavy sections should be avoided because of deleterious results in central areas. In general, the time allowed for heating to temperature should be 45 to 60 min per in. of cross section. The forging should then be held at temperature long enough to obtain uniform temperature throughout the mass.

Annealing. The purpose of annealing forgings is to refine the grain structure, increase the ductility, or soften the steel for ease of machining. Annealing consists of heating the metal to a temperature above the transformation range, holding it a sufficient length of time at that temperature, and then cooling it in the furnace or under other suitable conditions for uniform, retarded cooling.

Normalizing. The purpose of normalizing forgings is to refine the grain structure or to secure the highest combination of mechanical properties without resorting to quenching in a liquid medium. This treatment consists of heating the parts to a temperature above the transformation range, holding long enough to ensure uniform temperature throughout the mass, and cooling in still or agitated air. However, for uniformity in forgings of complicated shape and variable section, it is often desirable first to normalize the forgings at a temperature well above the transformation range, and to follow this treatment with one or more additional normalizing treatments at successively lower temperatures all above the transformation range. Varying reductions by plastic forging are usually associated with varying thermal histories, which may produce a nonuniform grain structure. Therefore, more than one normalizing treatment may be required for producing the desired refinement.

Quenching. For the larger sizes and for most alloy steels, the usual practice is to rough machine before quenching, in order to bring the size reasonably close to the finished dimensions and to ensure freedom from surface defects and scale. It is customary for the designer to provide large radii or fillets at sharp changes in section so as to reduce the hazard of cracking. Usually as sections increase in size, or as shapes become more irregular, the hazard of quench cracking is increased. It is recommended that liquid quenching be restricted ordinarily to parts 10 in. or less in diameter or thickness and, where possible, that forgings more than 7 in. in diameter be bored. The effectiveness of quenching a bored forging depends to a great extent on the ratio of the wall thickness to the diameter of the hole, and to the length. More highly alloyed steel is recommended for heavy-walled forgings where desired properties can be developed by cooling cycles conducted in air or in the furnace.

For developing higher mechanical properties if they are required, and also for realizing the effects of alloy additions, heavy sections are quenched after a suitable pretreatment. As composition and size become more critical, forgings are usually given a normalizing or annealing treatment, or both, to develop a uniform prestructure and machinability before heating for quenching. Forgings may be quenched in air blasts, oil or water. Decisions concerning liquid quenching procedure, however, must be based on proper consideration of the part to be quenched—that is, the shape and composition; on facilities for handling hot heavy sections; and on available quenching tanks of suitable size, with necessary circulation or agitation, and arrangements for liquid cooling.

* The members of this subcommittee are E. J. Edwards, *Chairman* (American Locomotive Company), C. A. Furgason (Ladish Drop Forge Co.), T. Ledin (A. Finkl & Sons Co.), A. P. Spooner (Bethlehem Steel Company), J. A. Succop (Heppenstall Company) and J. White (Erie Forge Company).

Care must be used in choosing the time and temperature at which the forging should be removed from the quenching medium. If removed while too hot or too cold, the piece may crack. Experience in quenching heavy sections should govern the temperature at which the forging is to be removed from the quenching medium. Large sections do not cool uniformly throughout; central areas cool more slowly and require more time. Forgings are usually permitted to reach uniformity in temperature after being removed from the quenching medium before tempering. If the sections are large or irregular, this equalizing can be done best in a furnace with temperature controlled at the point desired. Quenched forgings should never be allowed to become cold before tempering. However, after liquid quenching, especially with alloy steels, it is advisable to equalize at some temperature below the transformation range so as to complete transformation and ensure stability. This same procedure may be employed after normalizing or air quenching.

Tempering. Normalizing is usually followed by tempering to improve ductility or to adjust the mechanical properties otherwise to meet specifications. Quenching is always followed by tempering, partly for the same reasons and also to remove quenching stresses. Tempering after either normalizing or quenching, will follow the same procedure as described above under Heating, except that the holding time will be increased for quenched parts to ensure adequate toughness. Forgings that do not have abnormal variations in size may be cooled in air. If size and shape cause complications, controlled cooling rates may be necessary to ensure stability. Here again experience is an important guide in determining how forgings should be cooled from the tempering temperature.

Stress Relief. When maximum dimensional stability is required in the finished machined condition on quenched and tempered, or normalized and tempered large forgings, the part may be stress relieved before the last light tool cut. This cycle is similar to the tempering procedure, except that the temperature for stress relieving is usually about 50 F or more below the tempering temperature.

Straightening. When straightening is necessary it is usually performed slightly below the tempering temperature. Often a part is straightened during the cooling after tempering, at a temperature above 400 F.

Mechanical Properties. Space does not permit a full discussion of the complex subject of mechanical properties of large forgings. Mass is the principal complicating factor. Most data available to the average metallurgist, concerning mechanical properties, have been obtained from metal heat treated as specimens 1 in. in diam. However, the heavier masses involved in large forgings, introduce greatly changed and varied rates of heating and cooling. These factors, in turn, affect the reaction rates of austenite formation and decomposition, and the temperatures at which these reactions take place, with resulting variation in the microstructure of the steel forging. This variation in structure naturally makes the mechanical properties obtainable from heavy masses different from those exhibited by test specimens 1 in. in diam. Optimum mechanical properties are usually developed in the outer areas of large forgings, decreasing in the inner portions—rather rapidly with carbon steel and less rapidly with steels of increasingly greater alloy content. In general, as the size of section increases, the values of mechanical properties may decrease within the forging. In the mechanical testing of large forgings the effect of mass on the properties of the steel is fully recognized. Test specimens are cut from locations in the forging (or in a prolongation of the forging) selected carefully to ensure that the property values obtained will be representative of the forging. (*See* "Mechanical Testing of Forgings", page 135.)

The American Society for Testing Materials offers several specifications for steel forgings. For general work, the ASTM Specifications A 235-46 (for carbon steel forgings) and A 237-46 (for alloy steel forgings) may be used. In applying these specifications, the engineer can usually benefit from consultation with a metallurgist experienced in production and heat treatment of heavy forgings.

Properties, Composition and Heat Treatment of Steel Gears

BY THE SUBCOMMITTEE ON HEAT TREATMENT OF STEEL GEARS*

THE PURPOSE of this article is to describe the properties and requirements that should be considered in the design and production of gears and sprockets, as well as to list the more commonly used steels and heat treatments for them. In addition, information is given concerning the application and limitations of processes used in treating gears.

Properties and Corrective Measures to Eliminate Failures. The primary purpose of gears and sprockets is to transmit power. The most important properties required in such parts are these: adequate load-carrying capacity, resistance to wear, to scoring, to pitting fatigue, to bending fatigue, and to chipping.

Adequate Load-Carrying Capacity. If gears are to perform satisfactorily, they must be designed and processed with great care, because poor design and processing can more than offset the best metallurgical practices. In general, the better the design, the smaller the gear required to do a satisfactory job. Design is important with respect not only to the form of the gear teeth, but also to the form of the entire supporting assembly, in order to avoid excessive localized loading of the teeth as a result of the shifting of the contact area under high service loads.

Area of tooth contact is very important in the life of a gear. In the cutting of gears intended for heavy-duty service, it is possible to compensate to some extent for distortion incident to heat treatment. In many plants, it is common practice to cut the gears after heat treatment. This practice, limited to gears that do not require high surface hardness, permits better control of tooth contact.

Resistance to Wear. Smooth abrasive wear is the normal type encountered in gears that have been in service long. This very slow removal of surface metal is not corrected by the use of EP (extreme-pressure) lubricants; in fact such lubricants might, under some conditions, produce slightly increased wear. High surface hardness is required for withstanding this type of wear.

Resistance to Scoring. Scoring or scuffing is rapid abrasive wear and results from the metal-to-metal contact of the gears and the subsequent welding of one contacting surface on another. Produced particularly at high speed and with heavy loading, scoring is usually considered to be the result of failure of the oil film, rather than of the metallurgical properties of the gear. For changing the chemical properties of the surface of the gear so that the surface will not weld, sulfur, sulfur chloride or other suitable material may be added to the lubricant in order to react chemically with the surface of the gear. Such lubricants are referred to as EP lubricants.

In some instances, treatment of gears to produce oxide, phosphate, or sulfide surfaces may give satisfactory results. This treatment prevents seizing and scuffing during the run-in period only; however, if conditions of operation are not too severe, such a treatment may be sufficient. Under very severe conditions, the EP lubricants are required. These lubricants are particularly needed for hypoid pinions and gears used in pleasure cars and trucks.

Resistance to Pitting Fatigue. Pitting of teeth, particularly at the pitch line, is a compression-fatigue type of

* The members of this subcommittee are W. E. Jominy, *Chairman* (Chrysler Corporation), H. B. Knowlton (International Harvester Company), Robert J. Peters (Warner Gear Division, Borg-Warner Corporation) and C. J. Tobin (Research Laboratories Division, General Motors Corporation).

failure. Repeated compressive stresses produce shear failure slightly below the surface, and eventually a small flake comes off, leaving a pit. Compressive-fatigue strength and resistance to pitting are approximately proportional to hardness. Case hardened gears are better in this respect than through-hardened gears of the oil-hardening type, since the surface layers of case hardened gears are usually harder. Structure may have some influence on resistance to pitting. Depth of case and hardness of core are also factors. If the case is too thin or the core is too soft to support the case, the tendency toward failure of the surface is increased.

Resistance to Bending Fatigue. Resistance to bending-fatigue failure is greatly influenced by the quality of finish on the surface of the fillets at the base of the teeth. Consequently, the machining practice employed in cutting a gear may have an important bearing on the suitability of a gear for a particular application. If the gear teeth have been finished by shaving, lapping, or grinding operations that do not include the fillet, it is essential for the initial machining of the fillet to leave a smooth surface.

Breaking of the tooth at the root is a bending-fatigue type of failure in which the rupture originates at the surface. The properties of the case are probably the most important as far as this type of failure is concerned. Soft spots in the fillet at the root of the tooth are conducive to very low fatigue strength. The fatigue resistance of the fillet may be increased appreciably by surface peening.

Resistance to Chipping. Chipping of clash-gear points is a type of failure frequently attributed to improper hardness or structure. In nitrided gears, chipping may be caused by the concentration of the white nitride layer at the edges. However, mechanical design has a great deal of influence on chipping. The engaging ends of teeth should be designed in such a way that tooth corners cannot be the first points of contact.

Classification of Gear Steels. Metallurgical practices on gears, with respect to the severity of service for which they are best suited, may be classified as follows:

Very heavy duty. Carburized low-carbon alloy steel with case depth more than 0.060 in.
Heavy duty. Carburized low-carbon alloy steel with case depth 0.040 to 0.060 in.
Medium duty. Carburized low-carbon alloy steel with case depth 0.020 to 0.040 in.
Medium duty. Carburized 0.30% C alloy steel with case depth 0.010 to 0.015 in.
Medium duty. Carburized 0.40% C alloy steel with case depth 0.005 to 0.010 in.
Medium duty. Cyanide-treated, medium-carbon alloy steel with case depth 0.003 to 0.010 in.
Medium duty. Oil-hardened, medium-carbon alloy steel, hardened from neutral or slightly carburizing atmosphere
Light duty. Cyanide-treated, low-carbon plain carbon steel with case depth 0.005 to 0.010 in.
Light duty. Medium-carbon plain carbon steel, heat treated to 250 Bhn
Extremely light duty. Free-machining type of steel from cold finished bar stock
Extremely light duty. Medium-carbon or low-carbon plain carbon steel, not heat treated

The steels for these various types of services are listed in the following tables. Table I shows the composition of the steels suitable for carburizing to obtain great wear resistance and load-carrying capacity. The hardenability rating of these steels is in the following order, beginning with the steel of lowest hardenability and using the hardenability of the uncarburized core as an index: AISI, A4027, A4620, A8620, A8720, A4820, A4320, A3312.

Table I. Steels Suitable for Carburizing in Order to Obtain High Wear Resistance and Load-Carrying Capacity

SAE Steel No.	AISI Steel No.	Composition, percentage C	Mn	Cr	Si	Ni	Mo	Al	P max	S max
3312	A3312	0.08 to 0.13	0.45 to 0.60	1.40 to 1.75	0.20 to 0.35	3.25 to 3.75	.....	.....	0.040	0.040
4027	A4027	0.25 to 0.30	0.70 to 0.90	.....	0.20 to 0.35	.....	0.20 to 0.30	.....	0.040	0.040
4320	A4320	0.17 to 0.22	0.45 to 0.65	0.40 to 0.60	0.20 to 0.35	1.65 to 2.00	0.20 to 0.30	.....	0.040	0.040
4620	A4620	0.17 to 0.22	0.45 to 0.65	.....	0.20 to 0.35	1.65 to 2.00	0.20 to 0.30	.....	0.040	0.040
4820	A4820	0.18 to 0.23	0.50 to 0.70	.....	0.20 to 0.35	3.25 to 3.75	0.20 to 0.30	.....	0.040	0.040
....	A8620	0.18 to 0.23	0.70 to 0.90	0.40 to 0.60	0.20 to 0.35	0.40 to 0.70	0.15 to 0.25	.....	0.040	0.040
....	A8720	0.18 to 0.23	0.70 to 0.90	0.40 to 0.60	0.20 to 0.35	0.40 to 0.70	0.20 to 0.30	.....	0.040	0.040
Nitralloy		0.38 to 0.43	0.40 to 0.70	1.40 to 1.80	0.20 to 0.40	.....	0.30 to 0.45	0.90 to 1.35	0.040	0.040

These steels for the most part are the most commonly used. It is generally accepted, however, that steels suitable for gears should contain 0.10 to 0.25% C, and should have sufficient alloy content to allow hardening in the section sizes in which they are used. Higher-carbon steels with shallower cases are sometimes used. Several types of nitralloy composition may be used in addition to the one listed in the table. McQuaid-Ehn grain size of 5 to 8 is usually specified.

The steels in Table II are suitable for gears that require medium wear resistance and load-carrying capacity.

Table II. Steels Suitable for Gears That Require Medium Wear Resistance and Load-Carrying Capacity

SAE Steel No.	AISI Steel No.	Composition, percentage C	Mn	Cr	Si	Ni	Mo	V	P max	S max

....	A9845	0.43 to 0.48	0.70 to 0.90	0.70 to 0.90	0.20 to 0.35	0.85 to 1.15	0.20 to 0.30	.....	0.040	0.040

These steels are the types most commonly used for gears, However, any steel that has the proper characteristics of hardenability, with carbon content from 0.35 to 0.50%, is suitable for gears of this class. It is now possible to purchase a number of types of alloy steels to meet specifications for hardenability. These steels have slightly broader chemical limits for the individual elements but the range of hardenability is controlled more closely. To designate these steels the regular SAE or AISI specification numbers are used with the suffix H. With regard to hardenability these steels are rated in the following order, beginning with the steel of lowest hardenability: AISI, A1345, A4640, A5145, A2345, A6145, A8645, A8745, A4145, A9845, A4340.

The steels listed in Table III are suitable for gears and sprockets that require only a moderate degree of strength.

SAE 1141 is suitable for gears to be subjected to very light service; this steel can be machined from cold finished bar stock and, used in the machinable hardness ranges, is one on which good surface finish can be produced and high cutting speeds employed. SAE 1050 steel is usually hardened by quenching in oil from 1475 to 1525 F. The

other steels in Table III are commonly quenched in water, brine, or caustic solution from 1500 to 1575 F. The design may determine whether the gear can be quenched in water. For instance, in very large gears the cooling rate may be so slow, even with water quenching, that satisfactory freedom from distortion can be obtained. With other designs, the distortion may not be of sufficient importance to offset the advantage of water quenching. The mill practice and grain size of the steel affect the hardness and the hardness penetration with any given speed of cooling. The residual elements, such as chromium, nickel, molybdenum and copper, have a marked effect on the plain carbon steels and may cause them to crack during water quenching. It is important to determine the quantities of residual elements present and the resulting hardenability.

Table III. Composition of Carbon Steel for Gears

SAE Steel No.	AISI Steel No.	Composition, percentage C	Mn	P max	S max
1035	C-1035.....	0.32 to 0.38	0.60 to 0.90	0.045	0.055
1040	C-1040.....	0.37 to 0.44	0.60 to 0.90	0.045	0.055
1045	C-1045.....	0.43 to 0.50	0.60 to 0.90	0.045	0.055
1050	C-1050.....	0.48 to 0.55	0.60 to 0.90	0.045	0.055
1141	C-1141.....	0.37 to 0.45	1.35 to 1.65	0.045	0.08 to 0.13

NOTE: Silicon content of 0.15 to 0.30% is desired. Steels may be purchased that have carbon ranges other than those listed in Table III.

Forging. The steels listed in Table I may be heated between 2100 and 2325 F for forging. The temperature of the forging furnace should be controlled automatically with pyrometers, and the finish forging temperature should not be lower than 1800 F.

The steels listed in Table II may be heated between 2100 and 2300 F, and the forging should be finished at a temperature not lower than 1800 F.

The steels listed in Table III may be heated between 2100 and 2350 F. The finishing temperature for these steels should be in the range from 1600 to 1850 F.

The upset method of forging is preferred because it permits proper grain flow. It is desirable to obtain uniform grain flow so that the direction of loading will be perpendicular to the direction of the grain. Uniform grain flow, which helps to minimize distortion in heat treatment, may be obtained by upsetting or by hammer forging. Where strength and minimum distortion are not essential, other methods of forging are permissible. When the section of a forging is large, particularly when made of deep-hardening steel, such as SAE 4340, it is necessary to cool the forging very slowly to prevent internal bursts.

Normalizing and Annealing. In general all forgings should be normalized and annealed. This treatment will refine the coarse structure produced by the forging temperature, minimize the distortion in subsequent heat treating operations, and improve the machinability. When gears are to be cut from bar stock, annealing or normalizing the bar stock may be advisable but is often unnecessary.

Table IV

Normalizing and Annealing of Steels Listed in Table I

Steel	Normalizing Temperature, deg Fahr	Cooling	Tempering Temperature, deg Fahr
3312	1650 to 1750	Air	950–1100
4027	1675 to 1750	Cool at maximum of 600 °F per hr to 900 F.	None
4320	1650 to 1750	Cool either in air or rapidly in furnace to 1200 F. Hold at 1200 F for 4 hr and cool in air.	None
4620	1650 to 1750	Cool in air or rapidly in furnace to 1000 F. Hold at 1000 F for 1 hr and furnace cool to 500 F.	None
4820	1625 to 1725	Cool either in air or rapidly in furnace to 1200 F. Hold at 1200 F for 4 hr and cool in air.	None
A8620	1650 to 1750	Cool either in air or rapidly in furnace to 1000 F. Hold at 1000 F for 1 hr and cool in furnace to 500 F.	None
Nitralloy	1750 to 1850	Cool either in air or rapidly in furnace to 1400 F. Hold at 1400 F for 3 to 4 hr. Cool in 1 hr to 1250 F. Hold at 1250 F for 1 hr and cool in air.	None

Normalizing and tempering or cycle annealing are commonly applied to steels listed in Table I. The hardness desired in these operations depends on the machining operations and the type of finish required for the particular gear. The hardness obtained depends on the cooling rate, which in turn depends on the size of the gear. The treatments given in Table IV are for gears of moderate size common in automotive and aircraft applications.

The normalizing temperature should be at least 25 F higher than the carburizing temperature.

For steel 3312, the desired hardness for cutting will be between 229 and 262 Bhn, although the type of finish required and whether or not broaching is to be used enter into the selection of this hardness range. The 4027 steel should have a Brinell hardness of 150 to 180. The remaining steels should machine well from 187 to 217 Bhn.

Table V

Normalizing and Annealing of Steels Listed in Table II

Steel	Normalizing Temperature, deg Fahr	Cooling	Tempering Temperature, deg Fahr
A1345	1600 to 1700	Cool in air or rapidly in furnace to 1200 F. Hold at 1200 F for 3 to 4 hr and cool in air.	None
A2345	1600 to 1700	Cool in air or rapidly in furnace to 1150 F. Hold at 1150 F for 2 to 3 hr, cool in furnace to 1100 F and cool in air.	None
A4145	1650 to 1750	Cool in air or rapidly in furnace to 1250 F. Hold at 1250 F for 2½ to 3½ hr. Cool to 900 F in 3½ to 4½ hr. Then cool in air.	None
A4340	1600 to 1700	Air	1200 F
A4640	1650 to 1750	Cool in air or rapidly in furnace to 1250 F. Hold at 1250 F for 2½ to 3½ hr. Cool to 900 F in 3½ to 4½ hr. Then cool in air.	None
A5145	1650 to 1750	Cool in air or rapidly in furnace to 1250 F. Hold at 1250 F for 2½ to 3½ hr. Cool to 900 F in 3½ to 4½ hr. Then cool in air.	None
A6145	1650 to 1750	Cool in air or rapidly in furnace to 1330 F. Hold at 1330 for 2 to 3 hr. Cool in furnace to 1250 F and then cool in air.	None
A8645	1650 to 1750	Cool in air or rapidly in furnace to 1250 F. Hold at 1250 F for 2½ to 3½ hr. Cool to 900 F in 3½ to 4½ hr. Then cool in air.	None
A8745	1650 to 1750	Cool in air or rapidly in furnace to 1250 F. Hold at 1250 F for 2½ to 3½ hr. Cool to 900 F in 3½ to 4½ hr. Then cool in air.	None
A9845	1600 to 1700	Cool in air or rapidly in furnace to 1200 F. Hold at 1200 F for 4 to 5 hr and then cool in air.	None

After these treatments, the Brinell hardness number should be between 187 and 229, except that for SAE 4340 the range will be 217 to 241. However, the Brinell hardness is not always indicative of good machining qualities. Microscopic inspection should show lamellar pearlite with a minimum of free ferrite or spheroidization.

If furnaces are not available for cycle annealing as listed in the tables, the gears may be annealed after normalizing, by heating to 1550 F, cooling in the furnace to about 900 F, and then cooling in air.

Normalizing of the Plain Carbon Steels Listed in Table III. For the plain carbon steels listed in Table III, heating from 1650 to 1750 F and then cooling in air will provide the desired hardness for machining. If the parts are unusually small, it may be necessary to cool in air to around 1300 F, to hold at this temperature for 2 hr and then to cool in air to room temperature.

Carburizing. When made from steels listed in Table I, gears may be carburized to any desired depth and treated as shown in Table VI. An activated salt bath, carburizing compound, gas or vaporized oil may be used in carburizing these steels. Salt is used for shallow cases.

Carburizing compound, most widely used, affords fair control of case depth. Accurate control of case depth and of carbon concentration at the surface, may be obtained by carburizing with gas or vaporized oil, using test specimens to determine the length of the carburizing cycle. The time required for carburizing is shorter when gas or

vaporized oil is used. Control of carbon content at the surface is desired, and in general, eutectoid composition is considered most satisfactory. When the work material has been cooled slowly after carburizing, it is then reheated and quenched instead of being quenched directly from the carburizing temperature. The reheating method is usually chosen in order to minimize distortion or to obtain greater surface hardness. This greater surface hardness results from the formation of martensite with less retained austenite than is formed when deep-hardening steels are quenched directly. Distortion may be increased because of excessive cold working with dull tools on the surface of green gear teeth. If the gears are reheated and quenched after carburizing, care should be taken to avoid decarburization during the operation.

Table VI. Carburizing Treatments

Steel	Carburizing Temperature, deg Fahr	Method of Cooling	Reheating Temperature, deg Fahr	Quenching Medium	Tempering Temperature, deg Fahr
3312	1650 to 1700	Pit or box	1475 to 1500	Oil	250 to 300
4027	1650 to 1700	Oil quench	.....	...	250 to 300
4320	1650 to 1700	Pit, box or oil quench	1500 to 1525	Oil	250 to 300
4620	1650 to 1700	Oil quench	.....	...	250 to 300
4820	1650 to 1700	Pit, box or oil quench	1475 to 1500	Oil	250 to 300
A8620	1650 to 1700	Oil quench	.....	...	250 to 300

Gas carburizing with the addition of ammonia gas is sometimes used for obtaining a hard, wear-resistant case.

Nitralloy steel is nitrided at 950 to 980 F for a sufficient time to give the desired depth of case. Before the nitriding process, the steel must be free from decarburization at the surface and must be in the quenched and tempered condition. The usual practice is to quench from 1700 to 1750 F in oil, and to temper at 1100 to 1300 F. After nitriding, 0.001 to 0.003 in. of metal should be removed from the contacting surfaces of the teeth to avoid surface flaking. Locations on carburized gears, where it is desirable to stop off the carburizing, may be copper-plated to a minimum thickness of 0.0007 in. On nitrided gears, the stop-off is accomplished by using tin 0.0003 to 0.0005 in. thick, or bronze with a minimum thickness of 0.0005 in.

Hardening and Tempering. The steels listed in Table II may be hardened by the treatments listed in Table VII.

Heating for Quenching. The gears are heated slowly and uniformly to the quenching temperature given in Table VII and are held long enough to ensure complete and thorough penetration of heat. The heating medium should be selected carefully to hold scaling to a minimum and to prevent decarburization. These purposes may be accomplished when the work is heated in a cyanide salt bath or in an atmosphere that will produce a light carburized case.

Quenching. The best results are obtained by free circulation of oil around the gear being quenched. Formation of gas pockets should be avoided. Special quenching fixtures are commonly used to minimize distortion. The speed of cooling depends somewhat on the rapidity of the circulation of oil. It is good practice to keep the temperature of the oil constant and between 110 and 130 F.

Water Quenching. Generally water quenching is used only on plain carbon steels containing less than 0.40% C. Quenching in cold water produces higher hardness but increases the danger of distortion and cracking. The heavier and more uniform the section and the lower the carbon and manganese contents, the more drastic may be the quench.

Quenching in warm water produces results intermediate between the effects of cold water and of oil quenching. Bath temperatures above 130 F are not recommended.

Brine or Soda Solution. Brine quenching is generally carried on in a solution of sodium hydroxide (caustic soda), or sodium chloride (common salt). The cooling rate of sodium hydroxide is higher. Sodium chloride solutions quench more slowly than sodium hydroxide and are corrosive to work pieces and equipment, but are safer to use. A ▮ to 10% solution of either of the materials is generally used. Higher concentrations are not much more effective. Temperature changes of brine solutions alter the cooling rate less than similar changes in water.

Below the temperature of martensite formation, quenching in brine is more drastic than quenching in water. Time quenching or quenching from brine into hot water or oil, may reduce the likelihood of distortion or cracking in parts of irregular shape.

The quenching of gears in brine, is not generally recommended because of the stresses induced by such drastic cooling.

Fused Salt Quenching. When the design makes special treatment necessary to avoid distortion, gears may be quenched in hot fused salt. Martempering, the process for hardening steel by this means, is discussed on page 629.

Time Quenching. Time quenching in water is used for those parts that cannot be completely quenched in water because of their composition or design. The operation is carried out by allowing the immersed section to remain in the quenching liquid only until the metal contains enough residual heat in the center of the heavier sections, to reheat the entire part to a temperature approaching that used for tempering. At this point, the part is withdrawn from the quench and allowed to cool in air until the residual heat has been distributed as evenly as possible throughout. After this, cooling may be carried on in any convenient manner. Automatic devices are desirable for timing the quench and ejecting the gear. If the time quenching is controlled carefully and the hardness range on the finished gear is not too narrow, the tempering operation may be omitted; but it is safer to temper the gear as though it had been completely quenched. Other variations of time quenching involve quenching in water and transferring to oil.

Cyanide Treatment of Gears. Sodium cyanide baths are used in the heat treatment of gears for cases less than about 0.008 to 0.010 in. deep. Treatment in cyanide is not favored for producing cases deeper than 0.010 in. The depth of the cyanide case, in many instances, varies from 0.003 to 0.005 in. Cyanide cases are used chiefly in connection with low-carbon plain carbon steels; the concentration of sodium cyanide in the bath is maintained at 18 to 30%. High surface hardness with correspondingly high resistance to wear, is obtained from treatment in cyanide. The light case obtained makes it necessary to finish the gears completely before cyaniding.

One distinct advantage of a cyanide treatment is that the work material comes out of the bath nearly as clean as before treatment. Cyanide baths are used extensively in hardening higher-carbon materials, such as the oil-hardening types of alloy steels (0.35 to 0.50% C), commonly used in gears. An appreciable volume of gears of this type have been treated in cyanide to keep the surface free from scale or decarburization. When cyanide baths are used primarily as a medium for clean heating, somewhat lower concentrations of sodium cyanide are maintained, although the concentration should not be less than 8%. Because greater emphasis is now placed on the improved wear resistance that can be produced by treatments in cyanide, the 18 to 30% concentration is preferred in most operations.

Tempering. In tempering, all sections should be brought to the proper temperature and held for 30 min to several hours, depending on the size and type of gear. One purpose of tempering is to relieve stress; therefore the lower the temperature used, the longer the gear should be held at that temperature.

Table VII. Hardening and Tempering

AISI Steel No.	Austenitizing Temperature, deg Fahr	Tempering Temperature, deg Fahr	Quenching Medium
A1345	1460 to 1510	425 to 475	Oil
A2345	1450 to 1500	425 to 475	Oil
A4145	1500 to 1540	425 to 475	Oil
A4640	1480 to 1530	425 to 475	Oil
A5145	1490 to 1540	425 to 475	Oil
A6145	1515 to 1565	425 to 475	Oil
A4340	1475 to 1525	425 to 475	Oil
A8645	1480 to 1530	425 to 475	Oil
A8745	1480 to 1530	425 to 475	Oil
A9845	1490 to 1540	425 to 475	Oil

Local Hardening. Teeth of gears and sprockets may be hardened locally by rapid heating and quenching of the surface. Both electrical induction and flame heating methods are employed. In both methods, the application of heat is so rapid that the surface layers reach the desired hardening temperature before the center of the gear tooth has become hot. These methods have proved particularly advantageous, with regard to cost, for the heat treatment of very large gears and sprockets, because a considerable proportion of the weight of the gear is not heated.

The objective of local hardening is to produce the desired surface hardness, the desired pattern of hardened and unhardened areas in the tooth section, and generally a good serviceable gear, free from distortion and harmful entrapped stresses. The pattern of hardened and unhardened areas in the tooth section can be examined readily by cutting and etching both longitudinal and cross sections in this area. The nature of the application determines the type of pattern required. Obviously the wearing surfaces of the gear teeth should be hardened. This hardening may be all that is required if bending and crushing stresses are very low. On the other hand, if bending stresses are high, the fillets at the roots of the teeth should also be hardened. When crushing stresses near the pitch line are high, it is desirable to have either a relatively deep hardened area, a fairly high core hardness, or both.

In carburizing and hardening, the hardened area naturally follows the contour of the surface—though not always, if induction or flame hardening is employed. The factors that govern the pattern of the hardened area include the size and shape of the gear, frequency of the induction circuit, power input, time of heating, degree of preheat, if any, and the period of delay before quenching. The shorter the heating time, the better the heated zone follows the contour of the surface. Very large gears are heated successfully with 9600-cycle circuits that will contour-harden gear teeth as small as 2-pitch. Contour hardening of fine-pitch gears may require 500,000 cycles or more. At present contour hardening of gears finer than 5-pitch is not done commercially. With finer pitch, the upper part of the tooth is hardened through and contour hardening ceases.

In flame hardening large gears, heat is usually applied progressively to one tooth at a time. The flame travels across the face of the tooth, and is followed immediately by a pressure quenching spray. This method is discussed in the article entitled "Flame Hardening" on page 647, where mention is made of the use of straddle-type heads that heat both faces of a tooth simultaneously.

The photograph on page 647 shows the cross section of a tooth hardened in this manner. It will be noted that the faces of the tooth are hardened down to the working depth, but that the fillets at the roots of the teeth are untreated and consequently soft. If there is sufficient distance between consecutive teeth, it may be possible to include the fillet in the heated and quenched area.

Large gears may be induction hardened, one tooth at a time. In small and medium-sized gears, the entire gear is usually placed in the induction field and the whole periphery is heated almost simultaneously.

In general, gears should be tempered below 450 F after local hardening to relieve stresses. The steel used for flame hardened and induction hardened gears usually contains 0.40 to 0.55% C. Either plain carbon or alloy steels may be employed, though the tendency is toward the use of plain carbon steels. Oil quenching is often used.

Both the induction and the flame heating methods are subject to a number of variations. The best results will be obtained only by careful study of these methods and by modification of the practice to fit a particular product.

Grinding. If gear teeth are ground after hardening, care should be taken to avoid the formation of grinding checks; overheating during grinding, which softens the surface of the gear tooth; and taking off too much of the case, if the gear is carburized or nitrided. It is good practice to etch the gear teeth in an alcohol solution containing 10% nitric acid to reveal any effects of overheating from grinding.

Hardness Testing. Hardness is generally tested with the Rockwell machine, using the 15-N scale for cases 0.010 to 0.015 in. deep, the 30-N scale for 0.015 to 0.025 in., and the C scale for deeper cases or for oil-hardened gears that are not carburized. It is recognized that production hardness tests cannot be made at the location where the hardness is most important—at the base of the gear tooth, for instance, or at the pitch diameter—but must be made at some location that indicates whether the gear has been properly hardened. A file test may be used for determining the presence of a soft skin on carburized and hardened gears. It is necessary occasionally to cut sections from production gears and make a thorough check on hardness at various locations.

Magnetic Particle Inspection. In the inspection of gears by the magnetic particle method, it is common practice to reject all that contain grinding checks, quenching cracks, straightening cracks, forging defects or seams.

Nonmetallic inclusions are judged by their severity and location in relation to stressed areas, but any true indications on the tooth surfaces are considered cause for rejection. It should be noted that indications at the roots of the teeth are likely to be overlooked because of powder build-up in this area and because of the tooth shape.

The Composition and Heat Treatment of Splined Shafts

By the Subcommittee on Heat Treatment of Splined Shafts*

THIS ARTICLE summarizes the processes to be followed for the heat treatment of splined shafts. A splined shaft is constructed so that it interlocks, either rigidly or with sliding, with another part or parts, such as gears. A splined shaft may have one or more keyways or one or more keys, but ordinarily the same shaft does not have both keys and keyways. Splined shafts are used in two general classes of work, automotive parts and machine-tool parts; examples are transmission shafts, axle shafts and propeller shafts. Any distinctions as to relative length or diameter would be rather arbitrary. Although steels other than those listed and discussed later, may be used successfully in splined shafts, the selections made are believed to be representative and adequate.

Design. Splined shafts are subjected to alternating stresses; hence their endurance limit in fatigue is important. The shaft should be designed to eliminate unnecessary necks and sharp corners where stresses might be concentrated. Fillets and machined grooves in splines should always be gradually rounded.

Stiffness is one of the necessary properties of some types of splined shafts, particularly of long shafts. Shaft designs should provide for sufficient section so that harmful deflection will not occur under the applied load. Shafts not properly designed may twist or bend, thus causing undesirable effects from alternating stress, vibration and the like, which will be manifested in the gears or other moving parts, as well as in the shaft. Heat treatment may raise the elastic limit of the steel, but it will not change the modulus of elasticity. For this reason, heat treated shafts are no stiffer than untreated shafts when operating below the elastic limit.

Distortion. This is the trouble most commonly encountered in the heat treatment of splined shafts. To avoid distortion, care must be used in all operations. Distortion

* The members of this subcommittee are George M. Enos, *Chairman* (Purdue University), H. Bates (Fairfield Manufacturing Co.), H. Stanley Binns (Cincinnati Milling Machine Co.), A. H. d'Arcambal (Pratt & Whitney Aircraft), L. A. Danse (General Motors Corporation), H. B. Knowlton (International Harvester Co.) and E. O. Mann (Chevrolet Division of General Motors Corporation).

includes volume changes as well as twisting or warping. Stresses induced by preliminary or roughing operations may need to be relieved by normalizing, annealing or stress-relief tempering before the final machining.

The carburizing and heat treating operations should all be carried out with extreme care. With some carburized splined shafts it may be necessary to avoid the "double treatment" (Method III of Table I), and to carburize at a lower temperature to minimize distortion.

Many splined shafts are made of bar stock having either a black, hot rolled finish, or a bright, cold drawn finish. Material treated in either way is more likely to be distorted later, than a properly normalized forging; therefore when minimum straightening is essential, splined shafts made of bar stock should be normalized in the same way as forgings, unless the straightening operation is considered absolutely necessary on the finished shaft. If hot rolled or cold drawn bar stock is used, it is essential that 1/64 to 1/32 in. should first be machined from the outer surface to insure a clean surface for hardening.

Keyways in a splined shaft may cause distortion in quenching. Unless designed with ample section, a shaft with a keyway has less stiffness than one carrying keys integral with the shaft. To minimize distortion in quenching, it is advantageous to have more than one integral key. These keys are equally spaced about the shaft to facilitate equal cooling and to balance the section.

Martempering will also minimize distortion; both Table I and Table II include this method of heat treatment.

Table I. Carburizing and Heat Treating of Carburized Splined Shafts

Carburizing Temperature, 1600 F and 1700 F (1650 F minimum preferred by many)
After carburizing, alternate methods
I Quench directly and temper.
II Cool in box, reheat once, quench in oil, temper.
III Cool in box, reheat (to refine core), quench in oil, reheat, quench, temper.

Steel[b]	Method II[a] Reheating Temperature, deg Fahr	Method III First Reheating[c] Temperature, deg Fahr	Method III Second Reheating Temperature, deg Fahr	For Any Method Tempering Temperature,[d] deg Fahr
1020	1400 to 1450	1550	1400 to 1450	350 to 425
1022	1400 to 1425	1575	1400 to 1425	300 to 400
2320	1325 to 1375	1540	1375 to 1400	350 to 500
2520	1350 to 1450	1525	1350 to 1400	275 to 400
3120	1375 to 1425	1550	1400 to 1425	350 to 500
3310	1375 to 1425	1525	1375 to 1400	350 to 500
3415	1350 to 1400	1525	1375 to 1400	350 to 500
4620	1420 to 1470	1525	1375 to 1425	275 to 400
4815	1375 to 1425	1600	1375 to 1425	275 to 400
8620	1425 to 1450	1575	1400 to 1450	300 to 400
8720	1425 to 1450	1575	1400 to 1450	300 to 400
9315	1375 to 1425 or 1500 to 1525	1525	1375 to 1400	350 to 500

(a) Many find it desirable to quench from 1450 to 1550 F.
(b) Only typical steels are listed from each type. The carbon range can be varied slightly without affecting recommended temperatures.
(c) An alternate treatment for alloy steels, which may minimize distortion, is to quench from the austenitizing temperature into salt at 400 F, hold according to cross section, cool to room temperature, and temper to requirements (martempering).
(d) Opinions differ considerably as to the tempering temperature that should be used for various steels. For some steels a lower tempering temperature, but not less than 275 F, may be desirable.

Chemical Composition of Steels for Splined Shafts. Two types of steel are commonly used for splined shafts. These are the carburizing and the direct-hardening types and include the following steels:

Carburizing Steels. 1020, 1022, 1320, 8620, 8720 2320, 2520, 3120, 3310, 3415, 4620, 4815 and 9315.

Direct-Hardening Steels. 1045, 1052, 1335, 8635, 8735, 2340, 3140, 3250, 3450, 4140, 4340 and 6150.

Selection of Steels for Splined Shafts. Splined shafts that are not to be highly stressed, can be made satisfactorily from steels 1020, 1022 or 1320. For sufficient stiffness, the shaft is sometimes designed large enough so that these steels may be used instead of alloy steels.

For small shafts that are to be carburized, steels 3120, 2520, 3310, 2320, 4620 and 4815 are satisfactory. If the diameter is more than 1½ in., the carbon content can be increased slightly without resulting in brittleness during quenching. For large shafts, steels 3415, 3120, 2320, 2520, 4620 and 4815 are satisfactory. Some users report favorably on the 9300 series for highly stressed splined shafts that have heavy sections.

Although the water-hardening steels can be used, it should be pointed out that water quenching may result in cracking, particularly if the design is such that the shaft will be susceptible to cracking. Steel 1045 is used for splined shafts but is not entirely satisfactory. It does not always respond uniformly to heat treatment, whereas 1335 does.

Steels 1022 and 1335, and others of this general type are used successfully in splined shafts. They machine freely, have good mechanical properties, and harden without difficulty.

In addition to these manganese steels, steels 1340 and 1345 are used to some extent for splined shafts. They machine less readily than the manganese steels listed, but have excellent mechanical properties and are of the oil-hardening type.

Almost any structural steel can be made into satisfactory splined shafts if the factors of *design, hardenability* and methods of *heat treatment* are properly correlated. Even the free-machining steels can be used, though conditions of surface stress and wear must be considered carefully if these steels are chosen, so they are not listed in the tables of recommended steels.

Table II. Hardening and Tempering of Direct-Hardening Splined Shafts

Quenching may be done in water,[a] oil[b] or salt,[c] as discussed in footnotes. Temper to requirements.[d]

Steel[e]	Quenching Temperature,[f] deg Fahr	Steel[e]	Quenching Temperature,[f] deg Fahr
1045	1475 to 1550	3140	1500 to 1550
1052	1475 to 1550	3250	1475 to 1525
1335	1475 to 1525	3450	1475 to 1525
8635	1475 to 1550	4140	1525 to 1575
8735	1475 to 1550	4340	1475 to 1550
2340	1425 to 1550	6150	1525 to 1625

(a) Steels 1045, 1335, 8630, 8730, 2330 and 4130 may be quenched in water.
(b) All the steels except those listed in Note (a), are classed as oil-hardening steels, and even those listed in Note (a) may be oil-quenched in small sections.
(c) *Martempering.* Any of the steels may be quenched in a salt bath at 400 F, held until equalized at that temperature (according to section), cooled in air to room temperature, and tempered.
(d) No exact tempering temperatures can be listed. *See text.*
(e) Only representative steels are listed. Carbon content may be varied to suit requirements; the usual upper and lower limits are 0.30 and 0.50%. For example, in the 8600 series, 8630 may be chosen for some uses; for other uses, 8650 may be chosen.
(f) Most of the fine-grained oil-hardening steels will harden in oil when quenched from within the range 1475 to 1550 F; some authorities express a preference for the range from 1525 to 1550. The range of carbon content selected may influence the exact temperature range chosen. Some prefer to heat the steels in a cyanide bath to the hardening temperature.

Normalizing and Annealing of Carburizing Steels. For normalizing, the carburizing steels should be heated to a temperature between 1650 and 1825 F. For best results in machining, the temperature should be at least 50 F above the carburizing temperature. Holding too long at elevated temperature causes excessive scaling if the furnace atmosphere is not properly controlled. The steel should be cooled slowly, to give the machining qualities desired.

Careful annealing of helical splined shafts is essential in order to minimize the movement of the helical angle or load in subsequent heat treatment.

Carburizing. The depth of carburized case is selected in accordance with the individual requirements. The methods of carburizing as given in this Handbook (pages 677 to 693) may be followed. The conventional pack carburizing process is satisfactory. Shafts should either stand vertically in the box or be supported to prevent sagging under heat. Uniform heating is essential; in some furnaces this may require horizontal heating at a possible sacrifice of straightness. In box carburizing, it is also important to be careful that the box is heated uniformly. The carburizing temperatures and the heat treatments for carburized splined shafts are given in Table I.

Quenching Treatments for Carburized Splined Shafts. There are several quenching treatments that may be given: (1) a direct quench from the box, (2) a single or (3) a double quench after cooling in the box, or (4) martempering. The factors that govern the choice of methods are: (*a*) shock resistance desired, (*b*) grain growth characteristics of the steel, (*c*) distortion. In some plants, experience has shown that suitable impact values and minimum distortion are obtained for certain steels by quenching directly from the box. However, it is common practice to use a single quench when the steel has cooled in the box after carburizing. (*See* Method II in Table I.)

In the single quenching treatment, it is advisable to use lower carburizing temperatures, and if the structure is coarse after carburizing, it is advisable to use the higher reheating temperature listed in Method II, Table I. It is, of course, desirable to hold distortion to a minimum. When steels are selected that do not coarsen at the carburizing temperature used, distortion is held to a minimum by direct quenching from the box, by a single reheating after cooling in the box, or particularly by martempering.

The double quench, as given in Table I, Method III, will produce refinement of case and core and resistance to shock and impact. While this treatment can be given without the need for such great care in the control of grain size as is necessary in single quenching, it has the serious disadvantage that the added reheating is almost certain to cause serious distortion. Thus it may be preferable in many instances to control the grain size and to use only the single quench.

For hardening, it is suggested that the splined shafts be hung vertically from eyebolts in the furnace, and also quenched vertically from the same eyebolts for both single-quenched and double-quenched shafts. Splined shafts are always distorted somewhat in relation to the keyway. It may be necessary to quench in a fixture or on a machine after the final heating, so that the shafts will be so little distorted that they will be straight after grinding, when an ample amount of grinding stock is allowed. If this method is used, the straightening operation may be unnecessary in some instances.

Splined shafts can also be heated in a horizontal position in a continuous furnace, provided the supports are properly spaced. The shafts come out fairly straight, although they usually require some straightening.

Tempering Carburized Splined Shafts. In tempering, the highest temperature should be used that will give the desired hardness.

Normalizing and Annealing Direct-Hardening Steels. For normalizing or annealing, the direct-hardening steels for splined shafts should be heated openly, exposing maximum surface area, to a temperature of 1600 to 1700 F. Closer temperature limits, but within this range, may be desirable for certain steels. For this treatment the steels should be held at temperature only long enough to insure complete penetration of heat. From these temperatures the steels may be cooled in the air or cooled at a rate that will produce the desired machining qualities. A retarded cooling rate through certain temperature ranges, may be desirable in order to produce good machining qualities; for example, for steels 1335, 1340, 2345 and 6150.

Hardening and Tempering Direct-Hardening Steels. The quenching temperatures for the splined shafts made from direct-hardening steels are given in Table II, with notes concerning the quenching mediums that can be used.

Low temperatures, usually in the range from 300 to 475 F, are employed for stress relieving. The time will be longer than that required when a tempering range of 900 to 1000 F is used. For every type of steel there will be a "blue brittleness" temperature range that should not be used in tempering. The lower limit of this undesirable temperature range for tempering is usually about 500 F. If it is desired to temper at a temperature higher than 500 F and lower than 900 F, the tempering ranges suitable for the steel in question should be determined by reference to other sections of this Handbook, or by consultation with the maker of the steel. Selection of the tempering temperature is influenced by several factors: whether machining is to be done after hardening, what procedures are to be followed in straightening, and what final hardness is desired.

As an example, some of the hardening and tempering variations possible for steel 3145, may be considered, in their correlation with machinability. This steel may be quenched from the temperature range 1425 to 1450 F and tempered between 900 and 1000 F. The shaft is hardened vertically, with spline or keyway not cut, leaving ample stock for grinding. The keyway is then milled after the heat treatment. If the steel has been properly normalized and properly handled, straightening is rarely needed, but if necessary, straightening can be done at the tempering temperature. After tempering, the shaft is rough-ground to 0.010 in. oversize; then the spline is milled and the splined shaft is finish-ground.

If, however, the tempering range selected for steel 3145 is 650 to 750 F after quenching from the range 1525 to 1550 F, the difficulties in machining after heat treatment will be increased, as compared with results from tempering between 900 and 1000 F. The Brinell hardness number will be considerably more than 300, but if no machining is needed after hardening, this tempering temperature will be quite satisfactory for this steel. If steel 3145 is tempered in the range from 300 to 475 F, the hardness will be still higher. It should be noted that although a tempering temperature as low as 650 F is possible for this steel, many steels cannot be tempered in this range for reasons previously discussed.

Most medium-carbon alloy steels, when tempered to Rockwell C 35, can be machined at a reasonable cost. Although higher mechanical properties can be obtained, machining costs mount rapidly when the hardness is above Rockwell C 35. Somewhat higher hardness values can be tolerated on steel 4340, still maintaining machinability.

Splined shafts may be difficult to straighten after quenching. If the tempering temperature is to be in the low range, straightening is usually performed before tempering and immediately after quenching; that is, while the steel is still hot. If the tempering temperature is in the high range, straightening may be done after tempering, if desired, although it can be done with less difficulty at the tempering temperature. Care should be taken in the design of splines and keyways (if more than one is present) to keep them balanced about the shaft, thus minimizing distortion. Even with a single spline, it may be possible to jig-quench or machine-quench so that distortion will be held within grinding allowance. The use of vertical retort furnaces with controlled atmospheres also tends to minimize the amount of straightening and grinding necessary. Although all the steels listed will distort unless extra precautions are taken, steels requiring the higher quenching temperatures may have a greater tendency to distort. Straightening is easier if the grain size is controlled. Grain size from 5 to 7 is preferred.

Most of the steels listed are ordinarily quenched in oil, although steels 1045, 1335, 8630, 8730, 2330 and 4130 are usually classed as water-hardening steels. Steels having higher carbon content, or shafts of very small cross section, regardless of composition, should not be quenched in water.

The coolant is not specified in Table II. The coolant and quenching rate must be co-ordinated with the design and with the hardenability of the steel. This often requires experimentation before the best methods for a particular job are developed. For a further consideration of hardenability and its relation to size of section and rates of cooling, reference may be made to pages 489 to 502.

Finally, the use of martempering is recommended as a heat treating procedure to minimize distortion and to secure satisfactory properties. The procedure is listed in footnotes to Table I and Table II, and reference may be made to page 629 for further details.

The Composition and Heat Treatment of Steel Springs

BY THE SUBCOMMITTEE ON HEAT TREATMENT OF STEEL SPRINGS*

IN this article the composition and heat treatment of four types of steel springs are discussed. The products considered are small flat springs, large flat and leaf springs, small helical springs, and large helical springs.

Small Flat Springs

This section describes the heat treatment of small flat springs used for miscellaneous purposes. The practice discussed here includes only springs cold formed from strip or from blanks less than ⅛ in. thick.

Imperfections. Flat stock of the compositions listed is furnished commercially in various grades. The price varies with the care used during processing in order to insure freedom from defects. The best grades should be free from surface cracks, hairline seams, surface decarburization, slag inclusions, die scratches, localized segregations, slivers and cuts. Such defects are starting points for fatigue failures and may cause early fracture; thus they are detrimental to highly stressed springs or to those operating rapidly over a great number of stress cycles.

Carbon steel 1045 is used in a hard cold rolled condition, not hardened and tempered, for flat springs in light sections $\frac{1}{16}$ in. thick or less, which are not highly stressed and in which low cost is a major consideration. All the carbon steels from 1045 to and including 1095 can be obtained in the form of cold rolled strip, either annealed or pretempered, while 1060, 1074 and 1095 can be had in the pretempered condition in several ranges of Rockwell hardness, held to a mean, plus or minus two points. All these steels can also be obtained hot rolled in strips or flat bars, or hot rolled, pickled and oiled. This material is supplied in the "as-rolled" condition, not tempered and not annealed. It varies considerably more in thickness than cold rolled strip, but may be used when low cost is desired and inaccuracy of loading can be tolerated.

The alloy steels, 6150, 9260 and 8650, are ordinarily supplied in the annealed condition for hardening and tempering after forming, but these materials are used occasionally in a pretempered condition. They may also be obtained hot rolled in thicknesses of $\frac{1}{16}$ in. or more.

Table I. Chemical Composition of Flat Material Used for Small Cold Formed Springs

Steel	C	Mn	Cr	Si	V, min	Mo	Ni
Carbon Steels							
1045	0.43 to 0.50	0.60 to 0.90					
1060	0.55 to 0.65	0.60 to 0.90					
1074	0.70 to 0.80	0.50 to 0.80					
1080	0.75 to 0.88	0.60 to 0.90					
1095	0.90 to 1.05	0.30 to 0.50					
Alloy Steels							
6150	0.48 to 0.53	0.70 to 0.90	0.80 to 1.10	0.20 to 0.35	0.15		
9260	0.55 to 0.65	0.70 to 1.00	.....	1.8 to 2.2	...		
8650	0.48 to 0.53	0.75 to 1.00	0.40 to 0.60	0.20 to 0.35	...	0.15 to 0.25	0.40 to 0.70

NOTE: Phosphorus, 0.04% max in all steels. Sulfur, 0.05% max in carbon steels, 0.04% max in alloy steels

Heat Treatment. Small springs made from cold rolled or pretempered materials should be given only a "stress-relief" heat treatment to relieve forming strains. This treatment consists of holding the springs for 20 to 30 min at temperatures between 450 and 550 F for light springs of carbon steels, and as high as 725 F for alloy steels.

Springs made from carbon steels in the annealed or as-rolled condition should be heated uniformly to a temperature between 1450 and 1525 F and then quenched rapidly in circulating quenching oil held to a temperature of 110 to 140 F. Springs will scale when heated in an open furnace. If no scaling is desired, they must be heated for quenching in a furnace that has a controlled atmosphere free from oxygen or in a salt bath of suitable composition. As quickly as possible after quenching in oil, springs should be tempered at a temperature ranging from 680 to 800 F, depending on the hardness desired. When some permanent set is allowable, the hardness should be 40 to 44 Rockwell C. When maximum resistance to set is desired, the range should be 44 to 48 Rockwell C. Carbon steel springs should never exceed Rockwell C 50, because material harder than that tends to be brittle.

Alloy steel springs made from 6150, 9260, or 8650 should be similarly treated from a quenching temperature of 1575 to 1625 F, and tempered at 725 to 900 F, depending on hardness. These steels can be about four points Rockwell harder than the carbon steels because of the alloying elements they contain. They should be held at the tempering temperature long enough to permit complete penetration of the heat. The method of cooling after tempering is not important.

Other Kinds of Material. Certain grades of stainless steel, notably the 18-8 type (for example, AISI type 302), are used for applications where springs are subjected to moderately elevated temperatures.

Phosphor bronze, beryllium copper and brass are used when electrical conductivity is desired.

High speed steels are used where springs are subjected to temperatures as high as 850 F.

Large Flat and Leaf Springs

This section discusses the heat treatment of hot formed flat springs made of carbon or alloy steels. It includes only springs hot formed from bars ⅛ in. or more in thickness, of the type used for railway, automotive and agricultural equipments, and also for miscellaneous applications.

Imperfections. Because of the nature of the production process, flat hot rolled bars cannot be free from such imperfections as pits, rolled-in scale, hairline surface seams and surface decarburization. Round bars can be rolled oversize and centerless ground, removing enough material in obtaining the finished size to eliminate such defects, but surface grinding processes developed so far for flat bars are too expensive, unless low cost is not essential.

Defects should be held to the minimum obtainable by the best mill practice. All bars should be free from pipes or laps, and as nearly free as possible from carbide segregations or inclusions that might cause quench cracking.

Hardness. The steel as received from the manufacturers should be soft enough to permit the simple cold working operations of shearing, punching, trimming and bending without cracking.

Chemical Composition. Steels 1074, 1095, 6150, 9260 and 8650 are used for hot formed flat springs ⅛ in. thick or more, as well as for small flat springs (*see* Table I). Steels 5150 (0.48 to 0.53% C, 0.70 to 0.90% Mn, 0.20 to 0.35% Si, 0.70 to 0.90% Cr) and 4068 (0.63 to 0.70% C, 0.75 to 1.00% Mn, 0.25 to 0.35% Si, 0.20 to 0.30% Mo) are also used for flat springs ⅛ in. thick or more.

* The members of this subcommittee are E. H. Stilwill, *Chairman* (Chrysler Corporation), D. C. Green (Muelhausen Spring Corporation), N. E. Hendrickson (The Mather Spring Company), L. R. Steele (Eaton Manufacturing Company), E. W. Stewart (The William D. Gibson Company), J. R. Thompson (American Steel & Wire Company), R. S. Thompson (Washburn Wire Company) and F. P. Zimmerli (Barnes-Gibson-Raymond, Inc.).

Heating for Slotting, Nibbing, Spear-Pointing and Tapering. For these operations the bars should be heated uniformly no higher than 1800 F, in a suitable furnace.

Heating for Forming. For forming, the bars should be heated uniformly in a suitable furnace to the lowest temperature at which the steel will work satisfactorily; this temperature should never exceed 1750 F for carbon steels nor 1800 F for alloy steels. After forming, the springs should be air cooled until they become distinctly black.

Annealing. When annealing is necessary for machining, the steel may be heated to between 1250 and 1400 F with rate of cooling controlled according to requirements.

Table II. Heat Treatment of Hot Formed Large Flat and Leaf Springs

Steel	Normalizing(a) Temp, deg Fahr	Quenching(b) Temp, deg Fahr
1074	1525 to 1575	1450 to 1525
1095	1575 to 1625	1475 to 1525
4068	1550 to 1600	1500 to 1525
6150	1600 to 1650	1600 to 1650
9260	1600 to 1650	1600 to 1650
5150	1600 to 1650	1475 to 1525
8650	1600 to 1650	1600 to 1650

(a) These normalizing temperatures should be used as the forming temperature whenever feasible.
(b) Quench in oil at 110 to 140 F.

Heating for Quenching. When springs have been allowed to cool to a distinct black after forming, they should be uniformly reheated in a suitable furnace to the quenching temperatures given in Table II. The soaking time in minutes in the furnace, after the springs are heated to temperature, may be determined by multiplying the thickness in inches by 60. This is equivalent to a soaking time of 1 hr per in. of section thickness. The springs should then be quenched, preferably in a suitable fixture in an ample volume of circulating oil that is held at a temperature of 110 to 140 F. The springs should be held in the oil until they have cooled to a temperature no higher than 300 F.

Tempering. As soon as possible after quenching, the springs should be tempered at a temperature ranging from 680 to 800 F for carbon steels, and from 725 to 900 F for alloy steels, depending on the hardness desired. They should be held at the tempering temperature long enough to insure complete penetration of the heat. The method of cooling after tempering is not important. If a salt bath is used for tempering, a hot water dip will remove the salt film from the springs.

When some permanent set is allowable in carbon steels the hardness of these steels should be about 352 to 388 Brinell, and when maximum resistance to permanent set is necessary, the hardness should be about 388 to 444. For alloy steels under the same circumstances, the hardness should be 375 to 415 Bhn and 415 to 461 Bhn respectively.

Small Helical Springs

This section discusses the heat treatment of cold coiled small helical springs designed to be used for miscellaneous purposes. The practice includes only springs made from wire ½ in. or less in diam.

Imperfections. The various materials furnished for small helical springs are supplied commercially in several grades; the prices vary according to the care used during processing, in order to insure freedom from defects. The best grades should be free from surface cracks, hairline seams, surface decarburization, slag inclusions, localized segregations, die scratches, slivers, pits and cuts. Such defects are detrimental to highly stressed springs, or those operating over a great number of stress cycles, because they are starting points for fatigue failures and may cause early fracture.

Hardness. The wire as received from the manufacturer, whether carbon or alloy steel, pretempered or soft, should have uniform hardness in order to hold uniform dimensions in coiling or forming. All spring wire of $\frac{3}{16}$-in. diam or less, whether pretempered or soft, should coil on its own diameter as an arbor, and in larger sizes should coil on an arbor twice as large in diameter, without breaking or cracking the surface.

Chemical Composition. The chemical compositions of steel wires generally used for cold coiled small helical springs made from wire ½ in. in diam or less are given in Table III.

Hard Drawn Wire. Hard drawn wire is not pretempered, but, as the name implies, obtains its physical properties from the cold work of die drawing. This type of wire is made into springs that are given no heat treatment except for heating a short time to relieve coiling strains. In drawing, this wire is "process annealed" by heating to a temperature considerably lower than the transformation range, at intervals during the reduction. This treatment reduces the tensile strength enough to permit further reduction in diameter, but retains part of the cold work previously imparted to the wire without changing the structure. Hard drawn wire is of comparatively low quality and is not guaranteed to be free from surface imperfections such as hairline seams, and not guaranteed to harden without quench cracks. The wire is used ordinarily for low-stressed springs not subjected to severe duty.

Music Wire. Music wire is a cold worked wire supplied to the spring manufacturers for making into small springs without further heat treatment except heating to remove coiling strains. Commercial sizes range from 0.004 to 0.135 in. in diam, but this material may be obtained in sizes increasing to a maximum of about 0.250-in. diam. Music wire is drawn to higher tensile strengths and to higher torsional elastic limits than any other material available. These high mechanical properties are obtained by a combination of the high carbon content and many continuous passes or reductions in the drawing dies. Toughness is obtained from a process called "patenting", which consists of heating the rods just before the drawing process, by passing them rapidly through a furnace. The material is heated to a temperature somewhat above the transformation range and is then quenched in lead or air at a speed that produces a sorbitic structure. The wire will then stand a great reduction in diameter without developing brittleness, if the number of passes is sufficient and the reduction at any one pass is not too great. Music wire is supplied in a bright smooth finish and the best grades are quite free from surface imperfections. Such wire is purchased according to tensile properties, not hardness.

Table III. Chemical Composition of Steel Wire Used for Cold Coiled Small Helical Springs

Designation	C	Mn	P, max	S, max	Si	Cr	V
Hard Drawn ASTM A227-41	0.45 to 0.75	0.60 to 1.20	0.045	0.050	0.10 to 0.30		
Music Wire ASTM A228-41	0.70 to 1.00	0.20 to 0.60	0.030	0.030	0.12 to 0.30		
Oil Tempered ASTM A229-41 (A)	0.55 to 0.75	0.80 to 1.20	0.045	0.050	0.10 to 0.30		
Oil Tempered ASTM A229-41 (B)	0.55 to 0.75	0.60 to 0.90	0.045	0.050	0.10 to 0.30		
Tempered Valve Spring ASTM A230-41	0.60 to 0.70	0.50 to 0.80	0.030	0.030	0.12 to 0.30		
Chromium-Vanadium ASTM A231-41	0.45 to 0.55	0.60 to 0.90	0.040	0.050	0.15 to 0.30	0.80 to 1.10	0.15 min
Chromium-Vanadium Valve Spring ASTM A232-41	0.45 to 0.55	0.60 to 0.90	0.030	0.030	0.12 to 0.30	0.80 to 1.10	0.15 to 0.25
SAE 9260	0.55 to 0.65	0.70 to 1.00	0.04	0.04	1.80 to 2.20	.....	.....

Oil-Tempered Wire. This wire is furnished to spring manufacturers in a heat treated condition. No further heat treatment is necessary after the material has been coiled into springs except heating for a short time to relieve coiling strains. The composition ASTM A229-41 (A) is used for the sizes larger than $\frac{3}{16}$ in. or $\frac{7}{32}$ in., varying with the practice in individual mills; and the composition ASTM A229-41 (B) is used for diameters as small as 0.020 in., the usual minimum for this grade. In commercial quality, this material is in the lower price range and is not guaranteed to be free from seams. It is widely used for commercial springs that are not in the class of "high-duty" springs where fatigue life is of paramount importance. Oil-tempered wire varies in tensile strength according to diameter. The smaller the wire, the higher the tensile strength; wire 0.020 in. in diam has a minimum tensile strength of about 295,000 psi while wire ½ in. in diam has a minimum of about 175,000 psi. The elastic limit in torsion varies somewhat with composition and with variations in manufacturing procedure, but is usually at least 40% of the ultimate tensile strength.

Oil-tempered valve-spring wire, ASTM A230-41, is the best quality of carbon steel wire available for "high-duty" springs. It is not possible to produce even this wire so that every foot of material is free from pits, slight seams or similar defects. For extremely high-grade springs, such as valve springs for aircraft engines, the finished springs are subjected to a magnetic particle inspection to eliminate any springs with seams, and are also inspected visually at a magnification of about 8 or 10 diam to eliminate any springs that show pits or similar defects. Except for such special springs, this costly inspection is seldom used.

High-grade springs are usually shot blasted. This process has proved very beneficial for increasing the resistance to fatigue, because of the compressive stress trapped in the surface layers of the material by the shot peening.

Annealed Wire. Wire is supplied to spring manufacturers in an annealed condition, and is used for making springs that are to be hardened and tempered after coiling. After being process annealed to produce partial or complete spheroidization, the wire is drawn to finished size.

Most commercial springs of wire diameters less than ⅜ in. are made from hard drawn wire, music wire or one of the grades of tempered wire. Some of the larger springs that have wire diameters from ⅜ to ½ in. are made from annealed wire and are heat treated after coiling, particularly when the ratio of coil diameter to wire diameter is small, resulting in difficulty in coiling the oil-tempered material. Experience has shown that more uniform springs can be obtained by using the pretempered materials than by hardening and tempering after coiling. This is because the desirable properties of uniform hardness, toughness, freedom from surface decarburization and from quenching cracks, are more easily obtained by hardening the wire as a continuous strand than by hardening the springs after coiling.

Close-coiled or extension springs are usually made with a property called "initial tension", which is a preload or pressure between adjacent coils when free. Initial tension cannot be obtained in springs that are hardened and tempered after coiling, because the condition is one of residual stress, later eliminated by heating the springs above the transformation temperature for hardening.

Chromium-Vanadium and Silicon-Manganese Steel Wire. The commercial grade and the select grade of these materials are supplied in both oil-tempered and annealed conditions. They are subject to the comments previously made about carbon steels, concerning the desirability of the oil-tempered material for springs in preference to annealed material heat treated after coiling. Both of these kinds of steel wire are used chiefly in springs that are very highly stressed and are subjected to moderately elevated temperatures, in which an alloy steel will operate for a satisfactory life but carbon steels soften too much.

Other Kinds of Wire. Certain nonferrous materials, such as brass, phosphor bronze and other bronzes, are used to some extent in springs when electrical conductivity or resistance to corrosion is a consideration. Some high-nickel alloys and copper-nickel alloys are used for special purposes.

Certain grades of stainless steel have found a rather wide application in small springs, notably the 18-8 Cr-Ni type (for example, AISI type 302). This material can be drawn to tensile strengths almost equal to those of music wire, size for size. However, the elastic limit, as well as the endurance limit in fatigue, is unfortunately considerably lower than the corresponding properties in music wire. This 18-8 material is resistant to many acids and alkalies, and to ordinary atmospheric conditions. It is used at temperatures no higher than 600 F.

Beryllium copper has been used to some extent, particularly in electrical applications in which a spring must act as a conductor of current, because this alloy has higher conductivity than any other spring material.

High speed steels are used for springs that are subjected to operating temperatures lower than 850 F.

Stress Relieving. The hardening and tempering of springs after coiling should not be confused with the low-temperature heat treatment after coiling, which is applied for the purpose of relieving coiling strains. Stress relieving a spring formed from hard drawn oil-tempered wire or music wire, will increase resistance to permanent deformation.

Heating and Quenching. Springs made from carbon steels in the annealed condition should be heated uniformly to a temperature between 1450 and 1525 F, and should then be quenched rapidly in circulating quenching oil held at a temperature between 110 and 140 F. As quickly as possible after quenching in oil, springs should be tempered by raising to a temperature between 680 and 800 F, depending on the hardness desired. When some permanent set is allowable, the hardness should be 40 to 44 Rockwell C. When maximum resistance to set is desired, the range should be 44 to 48 Rockwell C. Carbon steel springs should never exceed Rockwell C 50, because brittleness may result.

Alloy steel springs should be similarly treated from a quenching temperature of 1575 to 1625 F and should be tempered at 725 to 900 F, depending on the hardness desired. This material can be about four points Rockwell harder than carbon steel with corresponding toughness and mechanical properties.

All springs made of carbon or alloy steels should be held at the tempering temperature long enough to permit complete penetration of the heat. The method of cooling after tempering is not important.

Spring of hard drawn music wire or oil-tempered wire should be heated to relieve coiling strains, and experience has indicated that 350 to 750 F is the most desirable range for these materials. After heating to temperature, the springs should be held in this range long enough to permit complete penetration of the heat.

Large Helical Springs

This section discusses the heat treatment of hot coiled helical springs of both plain carbon and alloy steels. The practice includes only large springs made from bar stock ½ in. in diam or more and of the type generally used for railway, automotive and agricultural equipment, but also used extensively for miscellaneous applications.

Imperfections. The bars should be as nearly free as possible from surface cracks, rolling seams, surface decarburization, pits, rolled-in scale, inclusions, carbide segregations, pipes and laps. Commercial bars in the as-rolled condition may not be free from these surface defects. If complete freedom from surface defects is necessary, centerless-ground bars must be used.

Hardness. The steel as received from the manufacturers must be soft enough to permit the cold working operations of shearing, trimming and bending without cracking.

Chemical Composition. Steels 1085, 1095, 6150, 9260, 4068 and 8650 are used for hot coiled helical springs made from bars ½ in. or more in diam. The compositions of these steels are given above. Steel 9262, which is the same as 9260 but with 0.25 to 0.40% Cr, is also used.

Most hot coiled springs are made from carbon steel. The alloy steels are used for special applications, requiring springs that are highly stressed or that must operate at elevated temperatures with little or no set. Alloy steels have been used largely in bar diameters wider than ⅝ in., because of greater hardenability and resistance to fatigue.

Heating for Tapering and for Coiling. For tapering, the bars should be heated in a suitable furnace to a temperature not exceeding 1850 F. For coiling, the bars should be heated uniformly in a furnace to the lowest temperature at which the steel will work satisfactorily. This temperature should never exceed 1750 F for carbon steels, nor 1800 F for alloy steels. After coiling, the springs should be cooled in air until they become distinctly black, except in special instances.

Annealing. When annealing is necessary for machining, the steel may be heated to the range between 1250 and 1400 F. The rate of cooling should be controlled according to the requirements.

Heat Treatment. The heat treatments for steels 1095, 4068, 6150, 9260 and 8650 are given in Table II. Steels 1085 and 9262 are heat treated in the same way as 1095 and 9260, respectively. The recommendations given for heating and for tempering large flat springs apply also to large helical springs.

Many large helical springs are produced successfully by quenching directly from the coiling operation. This involves careful controls, and the practice must be limited to springs large enough in bar diameter and short enough in bar length to maintain a proper quenching temperature immediately after coiling. In direct quenching, the bar should never be heated above the normalizing temperature shown in Table II.

Shot Peening. Shot peening is distinctly beneficial as a means of increasing the endurance limit of all of the spring steels in the sizes commonly used. Data concerning the effects of shot peening on the properties of helical springs are given in the article on page 243 of this Handbook.

Flame Hardening

BY THE SUBCOMMITTEE ON FLAME HARDENING*

FLAME HARDENING can be defined as a process of heating the surface layer of an iron-base alloy above the transformation temperature range by means of a high-temperature flame, and then quenching. In this process the fuel gas flames impinge directly on the work piece.

The treated layer can be varied from a thin skin obtained by heating quickly, to a substantial layer obtained by "soaking heat". The usual depth for most purposes is $\frac{3}{32}$ to $\frac{1}{8}$ in. of nearly fully hardened material. Because there is no alteration of the chemical composition of the work piece, a hardenable material must be used. This method must not be confused with carburizing, cyaniding or nitriding, since these processes require the addition or absorption of other elements.

Comparison of Furnace and Flame Hardening. Because of uniform heating, furnace hardening produces parts that are hardened all over. Flames permit selective hardening because they can be directed to localized areas. Small parts to be hardened all over and produced in large quantities can usually be hardened more economically in the furnace. In many instances where the parts are large or where only certain areas are to be hardened, flame hardening can be used.

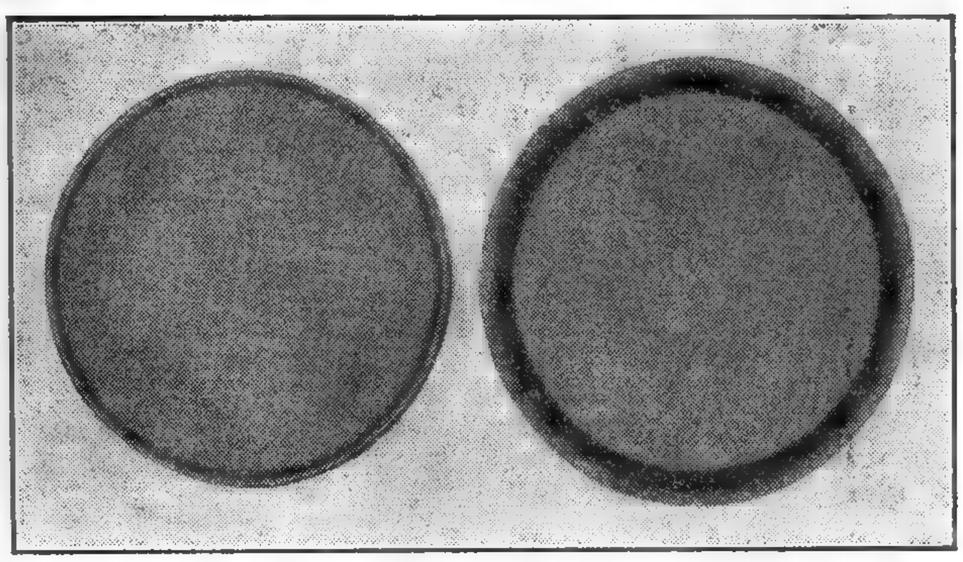

Fig. 1 Round bars flame hardened by the combination method. Light case and medium case. SAE 1045 steel.

Distortion. Flame hardening tends to minimize or eliminate objectionable distortion on many designs. However, thin pieces that are long in proportion to the cross section will distort, sometimes excessively, when hardened on one side. Often the procedure may be altered to reduce this effect. Pieces hardened symmetrically or on two sides have the least distortion. Long round bars should be annealed virtually free from stress. A water bath can sometimes be used to compensate for heating that is uneven or on one side only. Distortion is a problem in itself and must be studied, sometimes by experiment, to determine the best method for correction. Sometimes a change in design that does not affect the utility of the part will aid in the elimination of distortion.

Materials. *Steels.* Any type of hardenable steel, including stainless, can be flame hardened if the proper procedures are followed. The carbon content should be 0.35% or more for appreciable hardening. The best range for most flame hardening methods is 0.40 to 0.50%. The alloy content will determine the type of quench to be used. Straight carbon steels in the range indicated can usually be given a rapid quench. The quench for alloy steels can be varied from a rapid quench to air cooling, depending on the hardenability of the steel. Sometimes a quench using compressed air immediately behind the flames is followed by a quench using water. Full hardness cannot always be expected with the slower cooling rates. Typical hardness patterns in a flame hardened steel bar and in a gear tooth are shown in Fig. 1 and 2, respectively.

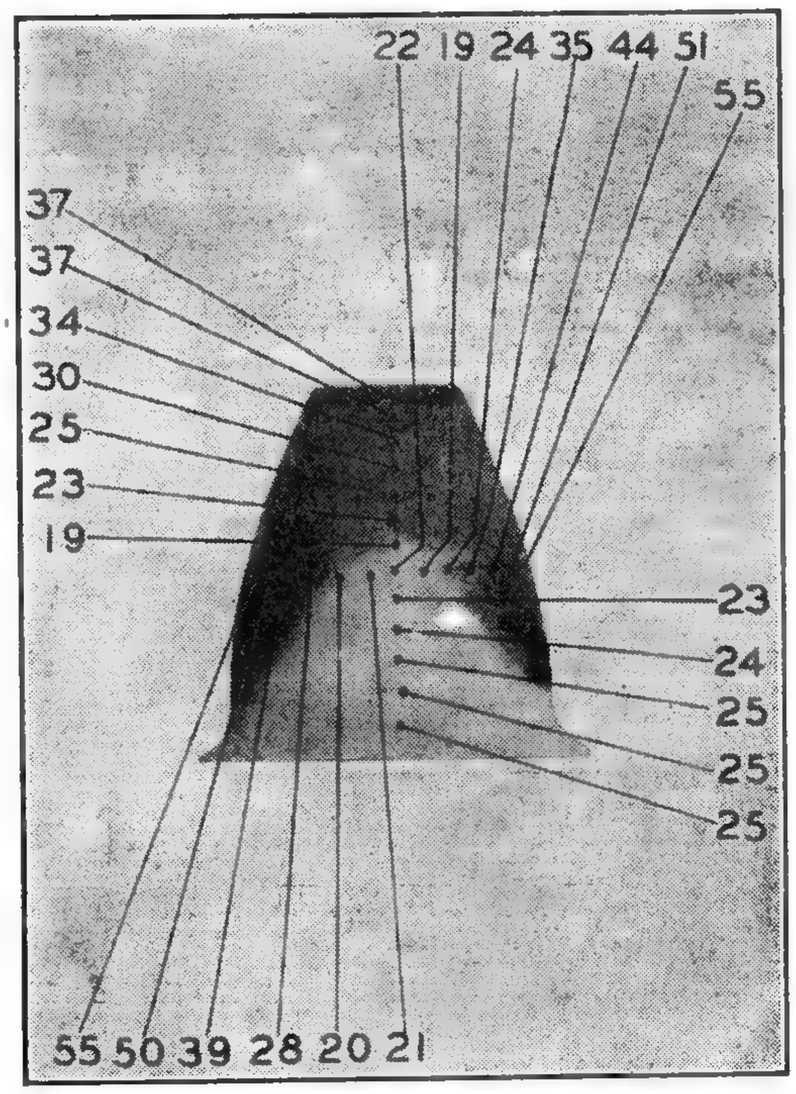

Fig. 2 Distribution of hardness in a gear tooth. SAE 4640 steel, progressively hardened without quenching.

Cast Iron. Pearlitic cast irons offer a broad field for the flame hardening process. Chilled cast iron has high resistance to wear, but chilled castings cannot be machined.

* The members of this subcommittee are H. V. Inskeep, *Chairman* (The Linde Air Products Company), Paul F. Berg (Selas Corporation of America), Carl E. Ernst (Gleason Works), A. L. Hartley (Cincinnati Milling Machine Co.) and Stephen Smith (Air Reduction Sales Co.)

Pearlitic cast iron can be machined to dimension and then flame hardened, greatly increasing the resistance to wear. In general, gray cast iron should have about 0.40 to 0.80% combined carbon for satisfactory hardening. Alloying elements such as nickel, chromium, molybdenum and vanadium, in the amounts used in cast iron, have little effect on the results. Cast iron is easily overheated and in general should be hardened at lower temperatures than steel. Any specific cast iron should be tested for hardenability, since poor results can be obtained even though the chemical composition may be correct. It has been found that the rebound type of device for measuring hardness gives more consistent and accurate results than the penetrator types on flame hardened cast iron. The penetrator types produce crushing of the matrix, causing scatter and low readings. Figures 3, 4 and 5 illustrate the results of flame hardening cast iron.

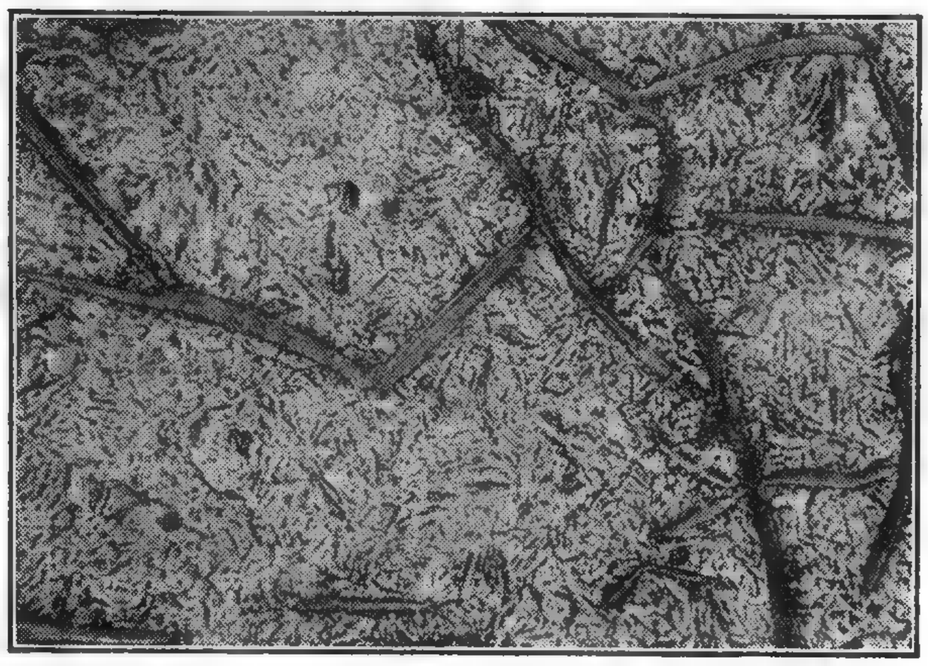

Fig. 3 Microstructure of cast iron, flame hardened by the progressive method. Composition 3.46% total C, 0.76% combined C, 1.58% Si, 0.76% Mn. Maximum hardness, 600 Brinell (converted from scleroscope). *Above,* case immediately below surface (× 500). *Below,* unhardened material.

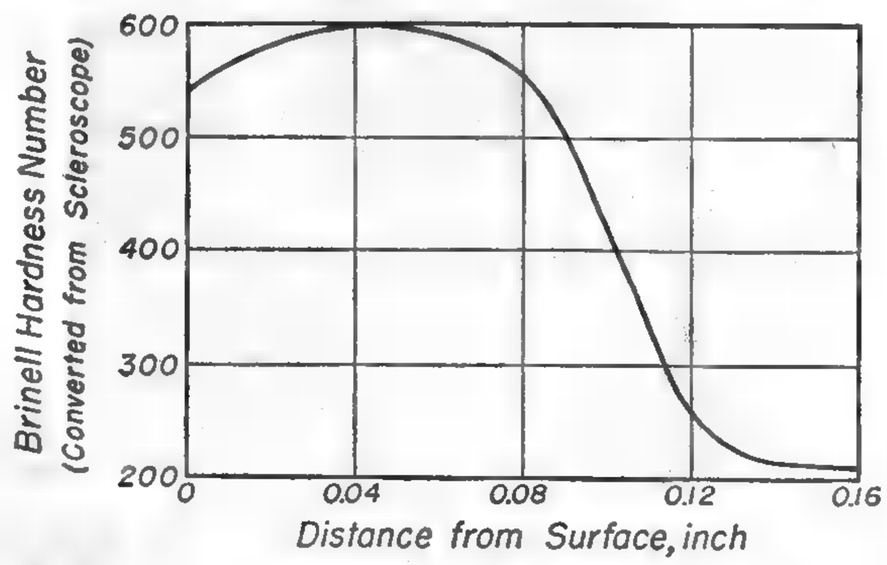

Fig. 4 Hardness penetration for the cast iron shown in Fig. 3.

Properties. This method of heat treatment can produce the optimum hardness on the surfaces subject to wear but leaves the core in its original condition; thus it is possible to treat the core for desired properties and then impart a hard surface layer without altering the core.

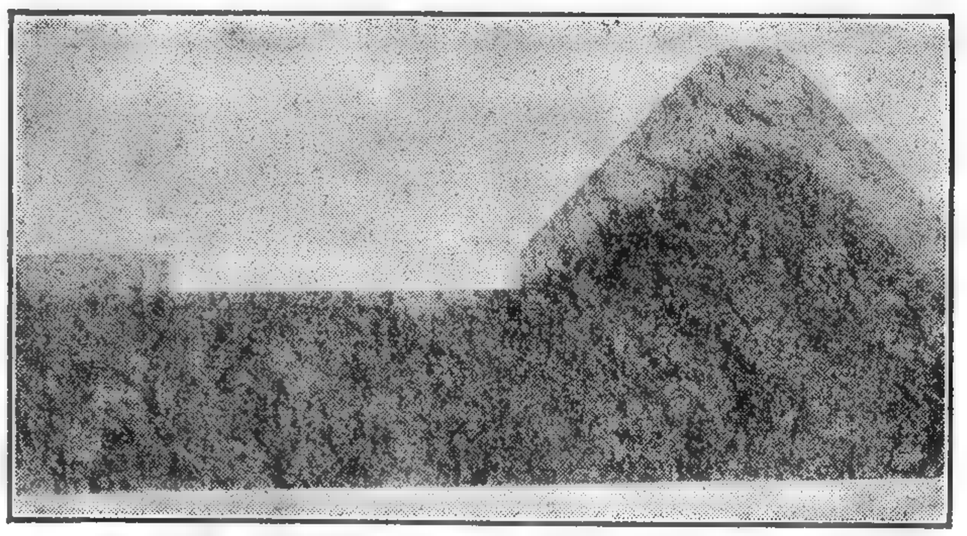

Fig. 5 Flame hardened sliding way section illustrating corner hardening. Cast iron.

Hardness. Flame hardening can produce the maximum hardness possible with any given type of steel if a rapid quench is used. In straight carbon steels, almost full hardness exists in 50% or more of the total layer affected by heat. The transition zone gradually reduces in hardness until core hardness is reached. Alloy steels, if water quenched, have a sharper gradient of hardness in the transition zone. If an air-hardening steel is quenched in air, the transition zone is deepened and the gradient of hardness is more gradual. Under some conditions of service, the deeper transition zone is desirable. Hardness on the surface is likely to be slightly lower when the hardened layer is thick. Thinner cases produce higher hardness at the surface, as illustrated by the curves in Fig. 6. By adjusting the rate of heat input and rate of quench, the relationship between fully hard and transition zone material can be varied.

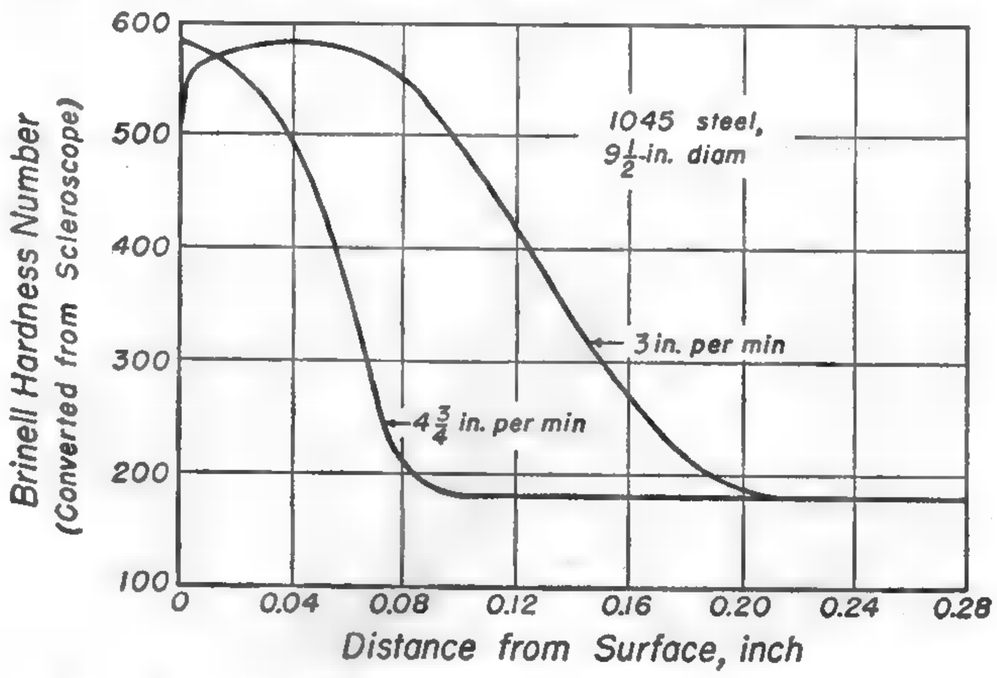

Fig. 6 Effect of progressive speed on the hardness penetration in a 9½-in. diam bar of SAE 1045 steel after flame hardening.

Methods. *The Stationary or Spot Hardening Method.* This method of flame hardening will accomplish hardening in spots or patterned areas. The work piece and the heating head are stationary. The size and shape of the desired hardened area will determine the design and number of flames in the heating head. For instance, stems for automotive engine valves require a single flame, and tractor-tread side bars that have a hardened area of 19 sq in. require a heating head with many flames distributed in an unusual pattern. The type of quench can be varied greatly by this method, easily utilizing still air, water spray and water or oil immersion.

Progressive Method. The progressive method implies a relative motion between the heating head and the work; either may move. The heating head is followed by a quench, usually a water spray. However, a quench in still air or a combination of compressed air and water spray may be used. The path of travel can be straight or of some other form—for instance helical on a large round bar. A slightly softer zone may exist at overlap points, as when the finish of a run meets the starting point on a round, or at the side of the heated path when parallel runs are made. Several mechanisms can be used for head or work travel, such as tractor-type flame-cutting machines, lathes or boring mills for rotary motions, or special types such as gear-hardening machines. Figures 2, 7 and 8 illustrate the result of progressive hardening.

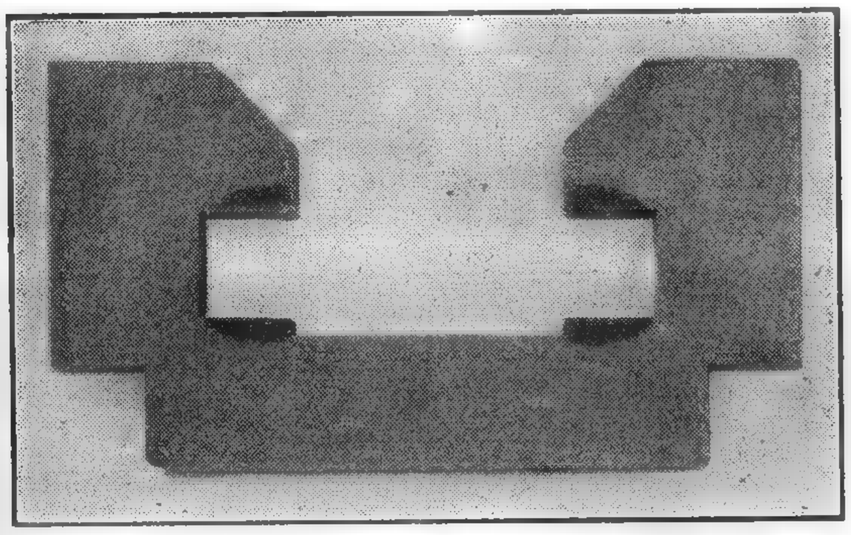

Fig. 7 T-bolt slot ½ in. wide, progressively hardened in two passes. Because of the narrow slot two heads were required. Bottom sides were hardened on the first pass, top sides on the second pass.

Spinning Method. The spinning method is used to harden areas on round sections, such as crankshaft bearings. The work piece spins in contact with flames from stationary heating heads. When the heating cycle ends, the quench is applied either by water spray or by immersion in a quench bath if the piece can be dropped from the chuck. Gears with 4DP teeth and smaller can be hardened by this method. Areas 7 in. wide on rounds 7½ in. in diam have been hardened by spinning. Parts hardened by this method are shown in Fig. 9 and 10.

Progressive Spinning. Round pieces of considerable length can be hardened by heating with a ring of heating flames followed by a ring of quench sprays. The cylindrical piece is revolved on its axis while the heating heads and quench move axially along the piece. The work piece is best placed vertically and revolved at a speed as high as is practical (at least 60 revolutions per inch of travel of the heating head), if the dimensions and balance of the article will permit. The higher revolving speeds produce the most homogeneous case. The diameters being hardened currently by this method vary from ¾ to 19 in. Internal surfaces such as mud-pump liners are also treated.

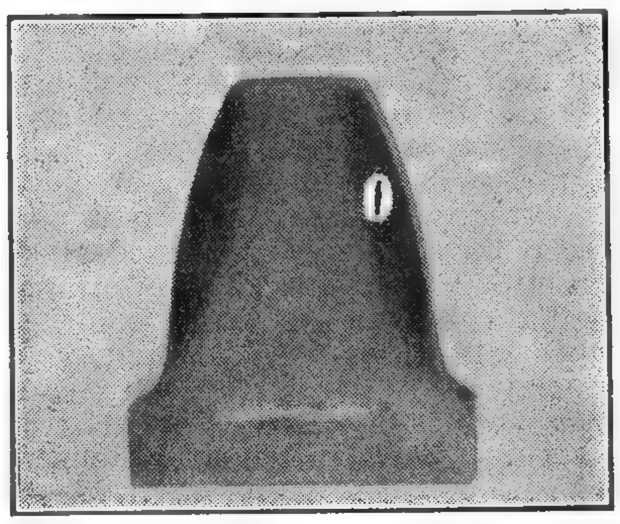

Fig. 8 Gear tooth progressively hardened with quenched SAE 1045 steel.

Equipment. Where production is limited and the areas to be flame hardened are small, the heating and quenching operations can be done by hand. A spot can be heated by a heating blowpipe with a single tip, held in the hand. When the temperature is raised sufficiently, heating is stopped and a stream of quenching medium is directed on the spot. Progressive flame hardening can be done by this simple method. The quench-spray tube is usually attached to the heating tip and the flame and spray are advanced over the path to be hardened. Hand operation is to be avoided if possible; a mechanized procedure is not influenced by the personal factor.

Heating Heads and Blowpipes. Most flame hardening applications involve areas that cannot be covered by a single flame. Multiflame heating heads are used, of the screw-in tip type or the drilled-face type. Both types are

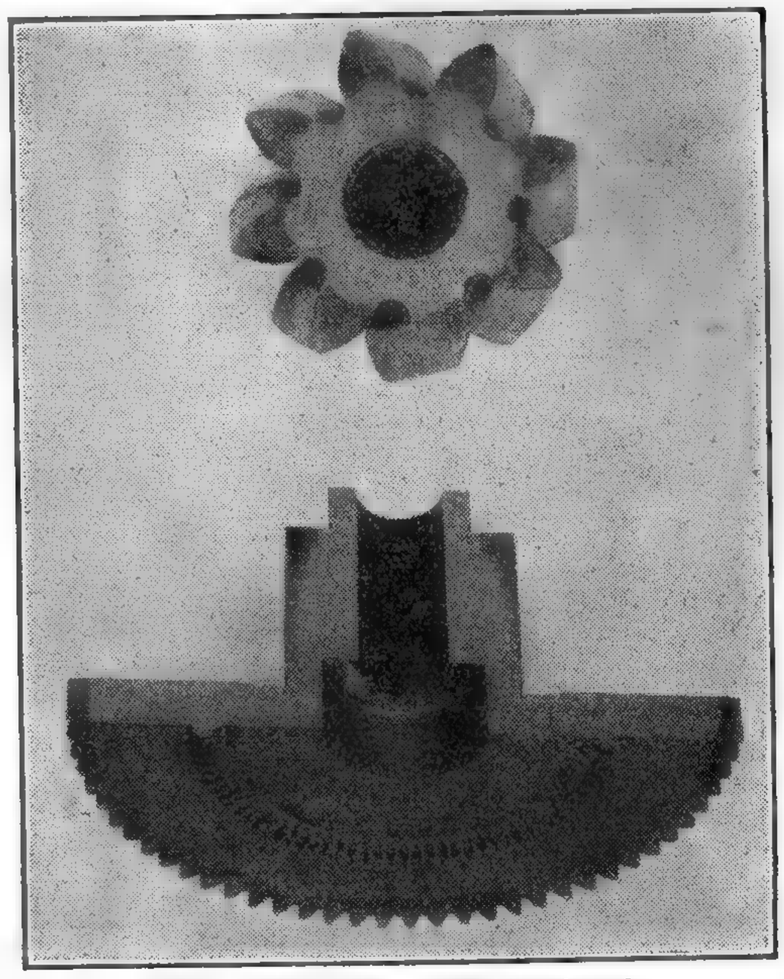

Fig. 9 Small gears, spin hardened.

available in standard sizes. To vary the coverage, tips are removed and plugs inserted. Heads with drilled faces are usually designed for specific applications and often the quench-spray holes are drilled in the same head. Water cooling of the heads is essential since operating conditions result in high temperatures.

The fuel gases are supplied to the heating heads by means of blowpipes designed to mix the fuel gas and oxygen properly and provide resistance to flashback. Blowpipes may have water-cooled connections to the heads.

Quenching Equipment and Mediums. *Equipment.* The design of quenching equipment is influenced by the type of heating head used and the type of steel to be hardened. Progressive operations must have full quench coverage over the heated band. This type of quench is designed to spray the quenching medium on the work ¾ to 1¼ in. behind the last row of flames when hardening 1045 steel. The spray should issue from the head at a 20-deg angle away from the flames. More sensitive steels will require a greater spacing between the flames and the quench. The principle involved is to obtain the maximum hardness without danger of cracking the steel. It should be remembered that the mass of steel underneath the heated layer aids the quenching action by withdrawing heat.

When a spray quench is used for the spinning method of flame hardening, the quench blocks should be in normal position while the heating cycle takes place. As soon as the flames are extinguished, the quench is turned on. The quench blocks should cover the heated band and provide enough quenching liquid to obtain full hardness. There should be enough quench points around the periphery to envelop the area completely with the quenchant. When the nature of the work piece is such that it can be removed easily from the heating position, dropping the part into a quench bath is sometimes advisable. This quench bath may be of any suitable composition.

Quenching Mediums. Water is the preferable quenching medium for all spray quenches. The use of oil in any form is to be strictly avoided in the vicinity of heating equipment that uses oxygen. If the quench blocks are designed for a maximum rate of cooling, variation in the rate can be obtained by reducing the water pressure supplying the quench. Increasing the distance between the last row of flames and the point where the quench impinges will allow the mass of metal to extract heat and further slow down the quench.

Compressed air passed through a quench block will further slow down the quenching rate and is useful in some applications. A quench in still air can be used with some types of air-hardening steels to provide a case that is shock resistant and particularly suited to gear teeth.

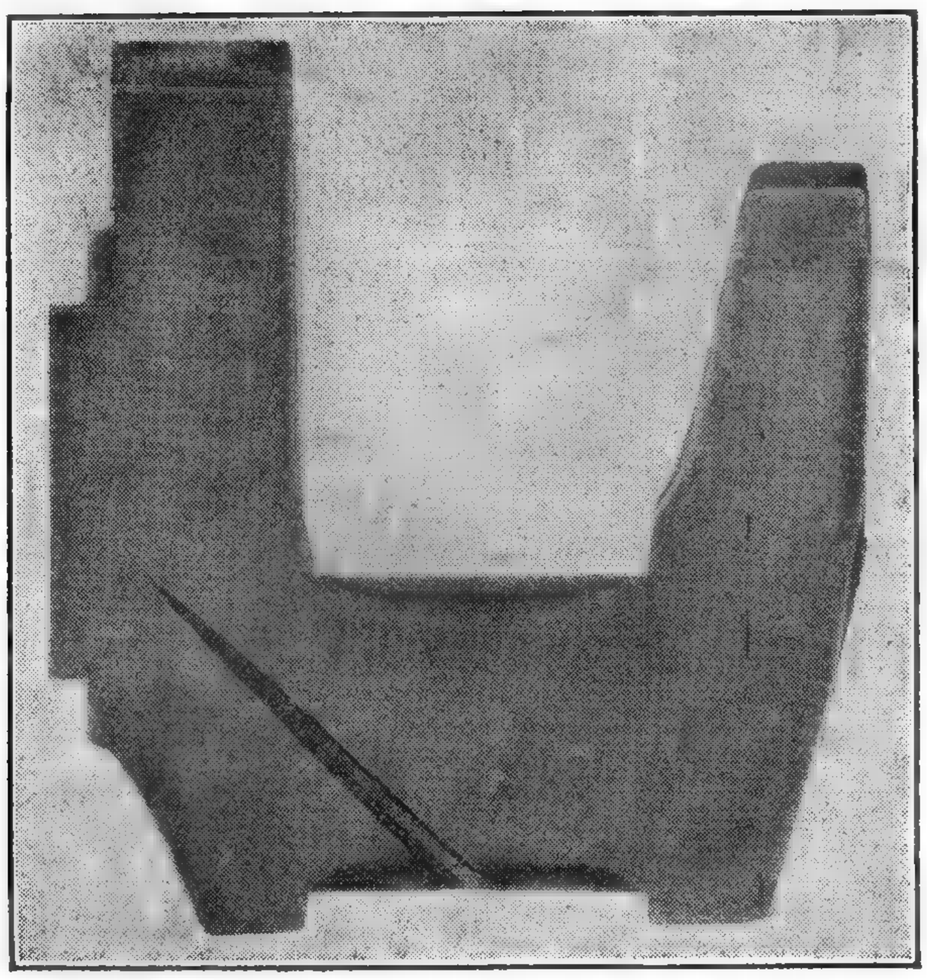

Fig. 10 Automotive crankshaft, spin hardened SAE 1045 steel.

Immersion quenches can vary in type in relation to the hardness desired and the type of steel used. The mediums usually are water, water and soluble oil, or oil.

Tempering. Flame hardened steel will respond to a tempering treatment as it would if hardened to the same degree by any other method. Standard procedures, mediums and temperatures can be used. However, since the flame hardening process can be applied to articles of considerable size, it is often difficult to find tempering equipment that has sufficient capacity.

Large articles are usually hardened by the progressive method and can be tempered at the same time by the simultaneous flame hardening and tempering process. This process consists of hardening progressively with a heating head and quench, and simultaneously reheating the hardened surface with a heating head spaced a short distance behind the quench. The reheating or tempering head must be designed correctly in regard to number and size of flame ports to produce the desired temperature in the flame hardened case at the flame hardening speed. Exact and final adjustment can be made by varying the flow of gas through the head. This simultaneous hardening and tempering process finds its greatest value in treating the larger articles, but it can be applied economically to smaller pieces as well.

Controls. Manufacturers of heating heads and blowpipes can furnish valves and regulators for the control of gas pressures and flows. Manual operation of valves is satisfactory for many applications, but where timing must be precise or production large, devices can be used for the control of cycles. Such controls are best applied to the spinning method. Progressive or progressive spinning methods require motivating equipment to move the heads over the work at a constant speed. Gases are usually turned on and off manually in these operations.

Machines. Progressive flame hardening usually requires a constant relation between the speed of the heating head and that of the work. Cutting machines are very suitable, since they have good regulation of speed and a wide range of speed. The larger sizes can carry considerable equipment without overloading. Machines for cutting shapes can be used to follow paths that are not straight, as is necessary for die hardening. A lathe can be used if the cross slide travel is adequate.

Progressive spinning requires special machines that will hold and turn the round in a vertical position. A platform is necessary that is movable at proper speeds to carry the heating heads and quench. The size can vary.

Lathes or special machines can be used for spinning operations. Production spot or pattern hardening is best done by machines built for the purpose. These machines usually consist of a rotating table carrying the work piece. The table is loaded at one point and the pieces are carried successively under the heating and quenching positions, or the piece may be kicked off into a quenching bath.

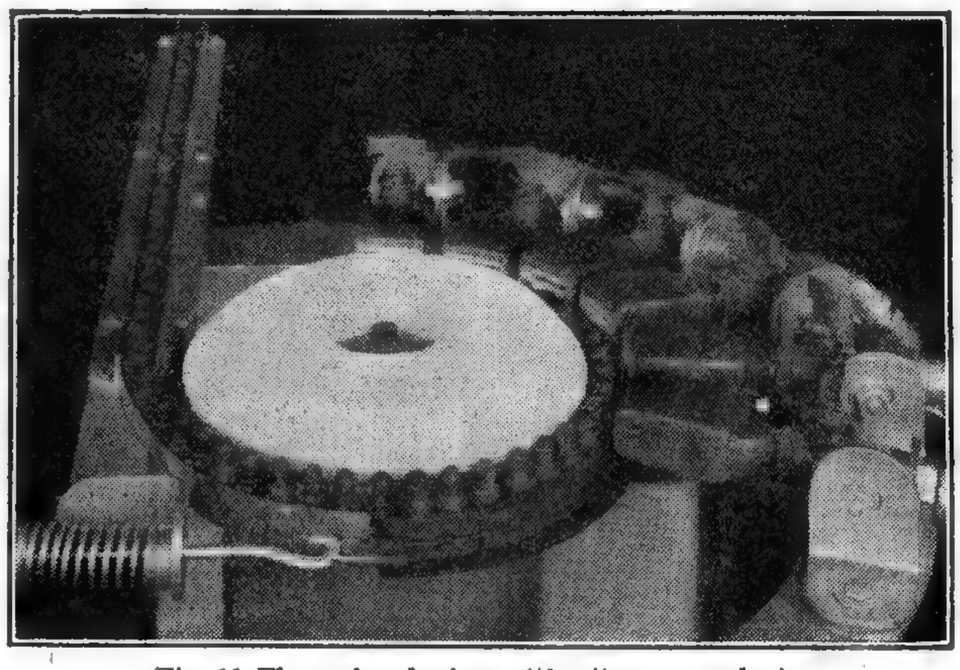

Fig. 11 Flame hardening with city gas and air.

Gear hardening can be done by hardening each tooth individually with special heating heads operating in pairs and heating and quenching both sides of the tooth simultaneously. The heads can be moved along the tooth by one of the cutting machines mentioned above. However, gears with 4DP teeth or smaller can be heated and quenched by the spinning method. One of the commercial gear-hardening machines will harden gears progressively without quenching when an air-hardening steel is used. Another gear-hardening machine will harden gears up to 12 in. in diam by the spinning method. Quenching is obtained by the immersion method.

Fuel Gases. Acetylene is the fuel gas most widely used for flame hardening. Mixing with oxygen at nearly a one to one ratio gives a neutral flame of high temperature, about 5630 F. Other fuel gases can be used for certain applications, provided equipment is designed for their use. The fuel gases can be mixed with oxygen or with air to produce flames of varying temperatures.

One combustion system in use today employs petroleum and natural or manufactured gas mixed with air and burned in special burners for flame hardening. One type of burner transmits heat to the work by means of convection and radiation; another type burns the fuel in a combustion chamber and issues the hot products of combustion (at approximately 3000 F) through a blast opening onto the work. The comparatively low-temperature burners supply a soaking heat that is advantageous for some spot hardening and spin hardening operations. Full hardness of the steel can be obtained by a suitable quench. The process can be used to spin harden gears of considerable diameter and to spot harden parts such as rocker arms for automotive engine valves, push-rod ends for airplane engine valves and ball peen hammers. Figure 11 shows a machine for hardening ball ends for push rods in airplane engines. Fuel gas costs for this process are negligible.

Gas Consumption and Speeds. Gas consumption for flame hardening will vary with the thickness of the case obtained. For example, when acetylene and oxygen are being used, thin cases about ⅛ in. thick will require about 0.14 cu ft each of acetylene and oxygen per sq in. Cases ½ in. thick will require 0.4 cu ft of each gas. For intermediate case thicknesses, the gas consumption is approximately proportional to the thickness of the case. Case thickness is the total zone affected by heat, as revealed by an ammonium persulfate or other suitable etch.

The speed of travel of the flame hardening head over the work material, or the time of heating for the spot or spinning method will vary with the thickness of case desired and the rate of gas combustion in the heads. The proximity of the quench spray to the last row of flames will affect the speed somewhat in the progressive method. Progressive and progressive spinning speeds can vary between 2 and 10 in. per min for most applications. The time required for the spot or spin method can vary from 10 sec for a thin case on small pieces to 1½ min for a ½-in. case on a rail end. The normal time for average operations is 30 to 40 sec.

Precautions. The flame hardening process is basically simple, but like all heat treating operations, certain variables are encountered. Speed of travel or time of heating should be held constant for uniform results. In the progressive method, the flames gradually heat the work piece in front of the heating head, and sometimes this effect must be compensated for by gradually increasing the speed of travel or by precooling. Pressures of fuel gas and oxygen should be controlled closely for uniform input of heat. Overheating of the surface should be avoided, since this condition accounts for most cracking problems. For precise work, it is advisable to examine test pieces metallurgically, altering speed, time or heat input for desired results.

Because flame hardening treats the surface of the steel, this surface and material underneath to the depth of heat treatment should be in the proper condition to respond to the operation. Decarburized areas will not harden. The surfaces to be hardened must be clean and free from scale, since scale interferes with both heating and quenching. Pits, blowholes, seams and laps at or near the surface will cause uneven heating, melting, or cracking during quenching.

Pieces properly flame hardened will have no scale or pitting. The discoloration produced on the surface can be removed by using an alkaline oxide-remover.

Stress relieving at approximately 400 F is recommended for all flame hardened articles except when the piece is quenched in still air.

Hardening temperatures can be judged by competent operators, but to the inexperienced the heated metal will appear colder than it actually is, because of the light from the burning gases; the consequent tendency is to overheat. It is difficult to see any temperature color when cast iron is treated properly by the progressive method. Metallurgical examination is the best method for establishing operating conditions. Overheated spots may appear under individual flames but, with properly designed heating heads, this effect is minimized and not readily detectable by microscopic examination.

Flame Softening

By H. V. Inskeep*

OXYGEN is commonly used to sever steel. A stream of oxygen projected from a suitable cutting tip attached to a cutting blowpipe is a useful tool that will sever steel either in sheet or in forms of considerable thickness. Every severing tool, whether saw, grinder or milling cutter, affects the surface that it cuts. The oxygen stream likewise has its effect and leaves the cut surface characteristically different from the base metal.

The chemical reaction of oxygen and steel during flame cutting evolves a great amount of heat. This heat raises the temperature of the cut edge to the melting point on the surface and above the transformation temperature for a shallow depth. The depth of the zone that is heated above the transformation point depends on the speed of cutting, the thickness of the piece and the amount of preheat emitted by the flames of the cutting tip. If this zone is cooled rapidly, hardening results when the carbon content of the steel is sufficiently high. This hardness can result in the cracking of the cut edge.

Straight carbon steels containing 0.30% C or less, do not harden sufficiently to prevent the use of flame-cut pieces in structures or in subsequent fabrication where bending is involved. However, steels containing alloying elements and steels containing more than 0.30% C may harden sufficiently, when cut by flames, to prevent the use of flame-cut pieces for some purposes.

When undesirable hardening occurs along a cut edge, oxyacetylene flames, applied by suitable equipment, can be used either to prevent hardening or to temper an already hardened cut surface. The term "flame softening" is applied to this process.

Some steels, such as the high speed types, certain highly alloyed ferrous materials, and several of the tool steels, will crack during flame cutting or very soon after, especially if they are in the bloom, billet or slab form. Total preheating, in a furnace or otherwise, before cutting, will prevent cracking in these instances. Preheat temperatures may vary from 400 to 800 F; the higher temperatures are used for the more sensitive steels.

The point where flame cutting produces a hardened surface that will be detrimental subsequently has not been determined for all steels and all uses of the flame-cut parts. To complicate matters, there is no one standard that can be used to meet all requirements. For structural uses, the flame-cut edges should meet satisfactorily the tests prescribed for the parent metal. These tests require liberal ductility and other properties within specified limits. In other applications, machinability is the only desired property. Where the flame-cut piece is to be heat treated and the edges are not bent during handling operations, the edges must not crack or check either during cutting or during cooling after cutting. Where the question of hardness or lack of ductility is important, examination or tests of the cut surfaces should be made. When material for test specimens is being cut, the lowest atmospheric temperature at which cutting will be done and the size and thickness of the piece should be duplicated, since these conditions all influence the results.

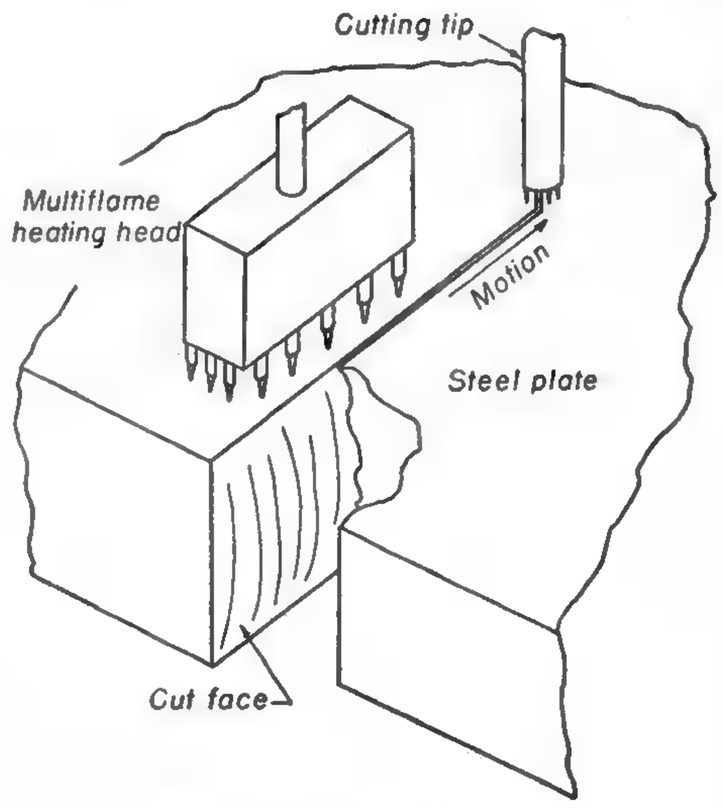

Fig. 1 Type I flame softening.

* The Linde Air Products Company, Newark, N. J.

Methods. Where excessive hardness or lack of ductility of a flame-cut surface indicates the need for softening, one of the following methods of flame softening may be used:

Type I. This type is used simultaneously with the cutting operation and the relationship of heating head and cutting tip is shown in Fig. 1. When the heating head is operated behind the cutting tip, the operation is known as "postheating". If the heating head operates in front of

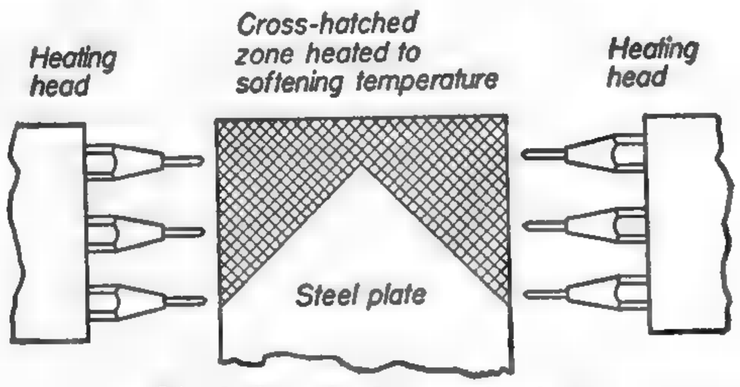

Fig. 2 Type II flame softening.

the cutting tip, the operation is called "preheating". The practical limit of plate thickness to which this type can be applied is 1½ in.

Type II. This type of flame softening is the same as type I except that heating heads are placed above and below the plate, as shown in Fig. 2. The plate can be preheated or postheated by this method. The practical limit of thickness is 3 in.

Type III. At times it is not possible or convenient to flame treat and flame cut simultaneously. When simultaneous treatment cannot be applied, the cut edge can be tempered by heating, as illustrated in Fig. 3. This tempering operation may be performed at any time after the cut has been made, providing the material does not crack during or after cutting. Cut surfaces 12 in. wide have been softened by this type of treatment, but even this thickness is not the limit, because heating heads can be made to cover even wider surfaces.

Choice of Methods. The choice of the flame softening method will depend on the type of steel being cut, thickness, economy, and whether or not it is expedient to cut and flame soften simultaneously.

There is a difference between the consumption of oxygen and acetylene in type I and that in type III. The consumptions are approximately 0.20 cu ft of each gas per sq in. of cut edge for type I treatment and approximately 0.06 cu ft of each gas per sq in. of cut edge for type III treatment. Type I treatment is accomplished simultaneously with cutting and there is almost no additional labor charge for softening. Type III treatment is separate from the cutting operation and requires a separate labor charge. The speed of travel for type III treatment, when using equipment that is available commercially, is 8½ in. per min along the cut edge. With these data, an approximate idea of the relative costs can be obtained.

To flame soften simultaneously with the cutting operation, results in considerable advantages when structural work is being done. Type I can easily be applied to any location on a plate where a cut is to be made. Type II is limited in scope to cutting applications where it is possible to carry the underside heating head on a bracket suspended

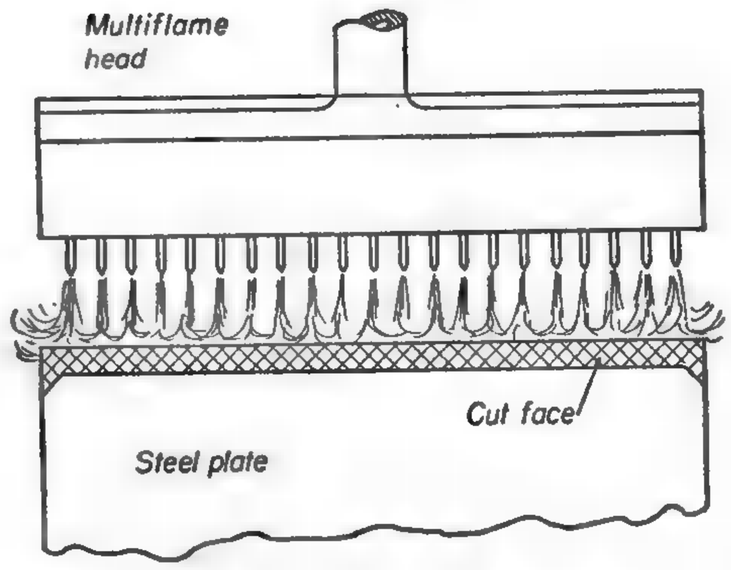

Fig. 3 Tempering the hardened zone on a cut face with a multiflame head that has a single row of flames.

from the main cutting machine. Care must be taken to see that the scrap from cutting does not drop on the equipment. Type III is used only after the cutting operation.

Temperatures. On straight carbon steels, the temperature of the surface during treatment is not critical except that it must be high enough to accomplish softening. Heating above the transformation range does not result in appreciable rehardening, since the cooling rate is slow. However, if an air-hardening steel is treated, care must be taken not to heat it above the transformation range. Overheating will reharden and underheating will not soften appreciably. Overheating of the plate surface under the heating heads must be avoided with air-hardening steels when type I and type II methods are used.

Effects of Flame Softening. Figure 4 shows the effect of flame cutting and softening on the hardness and ductility of the eight steels listed. Adequate softening has been obtained by the type I treatment.

Miscellaneous. Flame softening by means of a manually operated single or multiflame oxyacetylene blowpipe can be used in many ways. Spot softening can be done for machine work, such as cutting keyways, drilling holes, altering hardened dies, cutting threads and removing hard spots encountered in various machinmg operations on large castings. Temperature for hand operation is usually estimated visually. The softened surface can be tested by indenting with a small center-punch or chisel.

The Forging and Heat Treating of Tool Steels

BY THE SUBCOMMITTEE ON TOOL STEEL

THE purpose of this article is to outline the general procedures for the forging and heat treating of tool steels. This outline is given to avoid repetition in articles which follow, concerning the composition and heat treatment of particular types of tool steels.

Even when correct equipment and temperature are used, many hardening failures result from improper manipulation during heat treatment. Failures may also occur as a result of improper design. Some of the factors involved in such failures are discussed in the article on page 243.

Forging. The object of forging is to change the shape or size, improve the physical properties, refine the structure or reduce the waste of material in machining.

Heating for Forging. The temperature ranges to be used are given on page 657. The heating should be done with a minimum of decarburization and at a rate that will insure complete penetration through the steel. This requires a good control of the atmosphere in good equipment. Some of the high-alloy compositions, such as the molybdenum high speed steels, require extra precautions; for example, coating the surface with borax or some other suitable protecting material. For highly alloyed tool steels, such as high speed and high-carbon high-chromium, the heating time is about twice that required for carbon tool steel. Overheating and excessive soaking at forging temperatures must be avoided.

Forging Operation. Forging should start with light blows which can be increased as the metal starts to flow.

When to increase the force of the blows and when to stop and reheat are decisions chiefly at the discretion of the operator. Care must be taken to keep the steel within the proper temperature range and to effect a sufficient reduction to insure proper grain refinement. The steel can be reheated as often as necessary to complete the forging, provided the above conditions are observed.

Cooling. Slow cooling in an inert insulating material, such as lime or mica, is recommended to prevent possible cracking from forging strains. This type of cooling is not always required for carbon steels but becomes increasingly important as the alloy content increases; for the air-hardening steels cooling of this type is essential. It is advisable to begin the normalizing or annealing treatment before the steel cools to atmospheric temperature, but not before it has cooled well below the transformation range.

Normalizing. Normalizing involves heating steel far enough above the transformation range to dissolve all excess constituents and then cooling the steel in air. This treatment results in a more uniform grain size and tends to break up nonuniform structures. Normalizing is more important on pieces that have been forged. It should not be necessary on steel that has been annealed by the manufacturer, unless it has been forged subsequently. Steels that tend to air harden, such as high speed steel, are generally not normalized.

Rate of Heating. Heating for normalizing should be done in a manner similar to that described under heating for hardening. Correct soaking time is proportional to the size of the piece. Prolonged soaking will coarsen the grain, rendering subsequent refinement difficult.

Rate of Cooling. The material is cooled from normalizing temperatures in still air.

Annealing. Tool steel is annealed to soften it for machining or further processing and to put it in condition for further heat treatment. If it is necessary to reharden a tool for any reason, the tool should be thoroughly annealed before rehardening.

Packing. Steel to be annealed should be placed in a sealed container to keep out furnace gases. When pieces are small, they should be packed in cast-iron chips, lime, mica or other neutral material to prevent scaling, decarburizing, and too rapid changing of temperature. Care must be taken to keep the steel from contact with the container and to avoid the presence of scale.

Heating. The steel should be heated slowly and uniformly to the temperature desired (*see* page 657).

Holding at Temperature. The steel should be held at the annealing temperature long enough for complete penetration of heat and transformation. The time will increase with the weight of the charge and the alloy content of the steel; generally 1 to 4 hr will be sufficient.

Cooling. The steel should be cooled slowly, preferably in the furnace, or in mica or other good heat-insulating material. In general, the slower the cooling, particularly through the transformation range, the softer the steel. The higher the alloy content, the more slowly the steel must be cooled. The cooling rate varies from 10 to 50°F per hr, depending on the composition of the steel and the structure desired.

Stress-Relief Annealing. This process, sometimes called subcritical annealing, is useful in removing residual stresses induced by heavy machine work or other cold working. As indicated, stress-relief annealing is usually carried out at temperatures below the transformation range (1000 to 1200 F). In many cases it is safely done without surface protection, but for some tools packing is necessary to prevent scaling and decarburization. Air cooling may be used safely. This treatment often aids in minimizing warpage as well as breakage during hardening.

Tools are usually stress relieved after machining and before hardening, but it is often desirable to rough machine, then stress relieve before finish machining.

Hardening. *Heating for Hardening.* The rate of heating for alloy tool steels should be slower than for plain carbon steels and should be slower, the higher the alloy content. In general, the slower and more uniform the heating, the less the warping or change in size or shape, provided other factors are unchanged.

Heating for hardening is most rapid in molten baths, somewhat slower in open or semimuffle fuel-heated furnaces, and slowest in electric or complete muffle-type furnaces.

To avoid sudden changes in temperature, large or intricate tools should be charged at low furnace temperature (below 1000 F). During heating, the tool should be manipulated so as to heat all parts at as nearly the same rate as possible. It is often advisable to support the tool on jigs or fixtures in order to reduce warpage and give better heat circulation. It is good practice to turn or move frequently pieces that have a tendency to heat unevenly. When practical, it is advisable to heat long slender sections while they are suspended vertically.

Large Sizes. A range of temperature is usually given in recommendations of heating for hardening. This does not imply that satisfactory results can be obtained on any tool if held anywhere within that range. Generally the larger pieces are heated to the high side of the range and the small pieces are heated to the low side.

Holding at Temperature. Care should be taken to hold the tool at temperature long enough to insure uniform heating throughout the section of the piece. As noted in the specific tool steel articles, certain steels of higher alloy content will require more time at temperature to obtain comparable solution of the carbides. Excessive time at temperature may cause some grain growth and surface decarburization, particularly at temperatures well above the transformation range.

Furnace Atmosphere. Proper control of furnace atmosphere is important and varies somewhat with the type of steel and the temperature used. Certain types of steel, such as the manganese oil-hardening grades, tend to have a soft skin on the surface after quenching. A slightly oxidizing atmosphere will prevent this condition. On the other hand, the best results for hardening high speed and high-carbon high-chromium steels are obtained in a reducing atmosphere with high CO and minimum CO_2. Neutral liquid baths also give good results.

Effect of Scale. If tool steel is heated above a dull red heat while in contact with scale, even though in a neutral or reducing atmosphere, it will decarburize. Therefore, care should be taken to keep steel, furnace hearth and containers as free from scale as possible.

Thermocouples. For specific instructions see the article "Pyrometry", page 174 in this Handbook.

Quenching Medium. The quenching medium employed depends on the speed of cooling necessary to harden the particular steel. Sufficient volume of coolant should be provided to maintain the quenching medium at proper temperature for uniform results. The use of air is not recommended for agitating and cooling liquid baths.

Brine. Tools quenched in brine (10% salt by weight) will throw their scale more readily, producing a cleaner surface of more uniform hardness. Brine is a more uniform and more drastic quench than water, when used in still or mildly agitated baths. On pieces having considerable mass or requiring definite flow directions, sprays or geysers are necessary. Brine should be maintained at a fairly constant temperature, ranging from 60 to 80 F.

Water. When water is used for quenching, it should be held at a fairly constant temperature (usually 60 to 80 F). Fresh water is often aerated and may produce soft spots; therefore, water that has been previously boiled or has been frequently used is recommended. Using sprays or geysers is a great help in obtaining the desired hardness, by eliminating gas pockets and washing away any scale that may be present. Tools quenched in water should be agitated so as to cool as quickly as possible through the transformation range, and should be removed from the bath while still warm (below 200 F).

Oil. Oils generally give best results when used between the temperatures of 100 and 150 F. Quenching in cold oil of improper fluidity should be avoided. Some oils deteriorate faster than others; consequently, they should be reconditioned as often as necessary. Oil baths should be checked frequently for the presence of water. For quenchings tools from a cyanide or other salt bath a straight mineral oil should be used because this kind of oil will not decompose under such conditions.

Air. Certain types of tool steels harden during air cool-

ing. Air cooling may be accomplished in three ways: (1) air blast, which is the discharge from a high-pressure line; (2) fan air, which is the current of air discharged from a fan; and (3) still air, which is atmospheric air undisturbed by artificial circulation. When any one of the three methods is used, the tool should be held or supported so as to allow as nearly uniform cooling as possible. In the use of an air blast, care must be taken to apply the blast through a properly designed device and to avoid the presence of water in the blast.

Special Quenching Mediums. Unusual conditions often require special quenching mediums; for example, a solution of 5 to 10% sodium hydroxide in water, which has a tendency to overcome soft spots and nonuniform hardening of carbon tool steels. Mixtures of water and glycerin will produce rates of cooling intermediate between those of oil and water. For oil-hardening steels the glycerin content is comparatively high (60 to 90% glycerin) whereas for water-hardening steels the glycerin content is low (10 to 40% glycerin).

Quenching. Tools should be quenched in such a manner that warping is at a minimum. When tools are immersed, the formation of gas pockets can be avoided by vigorous agitation of the piece or by the use of sprays or geysers. It is important to have the cooling medium come in contact with all parts of the work to be hardened. Usually tools should not be removed from the quenching bath until they are below 200 F or the point where water boils on them, nor should they become cold in the quench. A good time to remove the tool is when all the surface is approximately 125 to 150 F. Then, if a rather large mass is involved, the tool should be held at this temperature until it becomes uniform in temperature throughout. This may be accomplished by placing the tool in an oil bath for the required length of time, after which it may be transferred to the tempering furnace.

Tempering. After removal from the quenching bath and before tempering, tools are always in a highly and nonuniformly strained condition and danger of cracking is most pronounced. Tools should not become cold before tempering, but should not be too hot to be held in the bare hands. Satisfactory tempering results are obtained by heating slowly and uniformly in a freely circulating medium. If a liquid is used, the tools should be placed in a wire basket for immersion, thus preventing contact with the sides or bottom of the tempering pot. When charging tools for tempering, the heating medium should be at a low temperature and the tools still warm.

Rate of Heating. Tools should be brought to temperature slowly to prevent rapid release of hardening stresses and warpage. Better results are obtained by holding at a lower temperature for a longer time. Generally the length of time should not be less than one hour at temperature. For recommendations on specific steels, reference should be made to the other articles on tool steel in this Handbook. Repeated tempering at the same temperature is usually more effective than one long tempering operation.

Rate of heat transfer will vary in different heating mediums. It is most rapid in metallic baths, less rapid in salt and oil baths and slowest in still-air furnaces.

Cooling from Tempering. Cooling from the tempering operation should be in still air because rapid cooling may induce strains in the steel.

Tempering by Color. Temper colors are the result of slight oxidation of the surface of steel when heated at low temperatures, and depend on time, temperature and composition of the steel. They indicate only the temperature of the surface and do not indicate that the steel has been heated uniformly throughout. Tempering by color is not conducive to uniformity. When necessity requires that tools be tempered by color, they should be heated slowly as in other operations and the temperature should be raised progressively to the point or color desired, after which further tempering is usually prevented by quenching or withdrawing from the heating medium. The quenching should be done preferably in oil.

Interrupted Quenching. High speed and other highly alloyed steels frequently are given an "interrupted" quench. consisting of cooling in oil to about 1000 to 1200 F, removing from the oil and cooling in still air to a temperature at which the steel can be handled with bare hands. A molten salt or lead bath, operating at 1000 to 1200 F, can be used instead of oil. The part is held in the bath a sufficient time to allow the steel to reach bath temperature, after which it is cooled in oil or air.

If the temperature of the steel, when removed from the quenching medium, is just above the temperature at which martensite begins to form during cooling (400 to 600 F), the method is called "martempering". Martempering generally aids in minimizing distortion and cracking in irregularly shaped parts of medium- or high-alloy steels. The cooling rates obtainable in the molten bath for martempering restrict this quenching method to steels that can be hardened in oil or air with conventional quenching.

Some tools, especially those made from oil-hardening steels, can be quenched into the low-temperature bath and allowed to transform isothermally. This method (austempering), as applied to oil-hardening steels, is limited to section sizes smaller than about 1 in. and tools which do not require a hardness greater than Rockwell C 60.

General Notes. *Salt Baths.* The salt bath method of hardening tools—particularly high speed steel tools—has greatly expanded with the increased use of molybdenum steels. This method is especially useful in hardening tools that cannot be ground after hardening. With good operating conditions tools can be produced free from decarburization and scale. The surface will be fully hard with very little distortion. For additional information, see the article "Salt Baths", page 283 in this Handbook.

Nitride Case. A nitride case will often give greater tool life and can be applied to any type of high speed steel. Such a case is produced by heating the finished tool in a cyanide bath at 1050 F for 15 min to 2 hr. The time at temperature depends on the depth of case desired. The usual time is about 30 min.

Cold Treatment. The purpose of cold treatment is to complete the transformation from austenite to martensite. The usual practice is to cool the steel to at least minus 90 F after quenching and before tempering, and to hold long enough to insure complete penetration.

Warping. The amount of warping during hardening depends on the shape of the tool, the kind of steel, the conditions of heating and the severity of the quench. In general, water-hardening steels warp more than oil-hardening, whereas air-hardening steels show the least distortion. Long thin tools warp more than short heavy ones.

Causes of excessive warpage include poor tool design, the use of the wrong type of steel, nonuniform or too rapid heating, improper support of the steel while heating, heavy machining, or cold working strains (*see* Stress-Relief Annealing under Annealing), insufficient removal of surface, nonuniform quenching and nonuniform or too rapid tempering.

Soft Spots. Common causes of soft spots are: decarburization; improper heating, quenching or bath agitation; gas pockets; tong contact; adhering scale; insufficient removal of surface; or defective furnace bottoms.

Straightening. When it is necessary to straighten a tool, the operation is best performed during cooling (on the "descending heat"). Straightening is done by peening, or bending in a vise or on a suitable press with an adjustable control and knife-edge rests, so that if one load does not satisfactorily straighten the tool, another load can be applied immediately. For straightening during cooling, the tools should be withdrawn from the quenching bath at a temperature from 500 to 600 F, which is just below the point where the oil ceases to flash, or for water-quenched tools, just where the water steams or dries off the tools immediately. Straightening may be continued to just above the M_s point (about 400 F for most grades). Air-hardening steels may be straightened at any time while cooling from the quenching temperature, preferably before they reach 400 F.

Classification and Approximate Compositions of Principal Types of Tool Steels

BY THE SUBCOMMITTEE ON TOOL STEEL

The purpose of this table is to give the reader a condensed list of the principal steels used by industry in each group. It should be understood that other steels have been found satisfactory for the specific applications covered in the chart, but they are not used generally. Except for the carbon tool steels, the quantity of each element present is given as a nominal percentage. This is done to simplify the chart and indicate the type of steel only. These figures cannot be used as a specification. In some instances optional (†) elements are listed. This means that these steels have found satisfactory application either with or without the element present, and generally no change of treatment is required.

The numerical designations employed in this table (IA, IIB2, VC3, etc.) are used to identify the same steels in the articles on heat treatment of tool steels in this Handbook (pages 660 to 676).

(a) These numbers are the ones used in the table of principal types of tool steels on page 656.

(b) The temperature at which to start forging is given as a range, the higher side of which should be used for large sections and heavy or rapid reductions, and the lower side for smaller sections and lighter reductions. As the alloy content of the steel increases, the time of soaking at forging temperature increases proportionately. Likewise, as the alloy content increases, it becomes more necessary to cool slowly from the forging temperature. With very high-alloy steels, such as high speed steels and air-hardening steels, this slow cooling is imperative in order to prevent cracking and to leave the steel in a semisoft condition. Either furnace cooling or burying in an insulating medium such as lime, mica, or silocel, is satisfactory.

(c) The length of time the steel is held, after being uniformly heated through at the normalizing temperature, varies from about 15 minutes for a small section to about one hour for large sizes. Cooling from the normalizing temperature is done in still air. The purpose of normalizing after forging is to refine the grain structure and to produce a uniform structure throughout the forging. Normalizing should not be confused with low-temperature (about 1200 F) annealing used for the relief of residual stresses resulting from heavy machining, bending and forming.

(d) The annealing temperature is given as a range, the upper limit of which should be used for large sections and the lower limit for smaller sections. The length of time the steel is held, after being uniformly heated through at the annealing temperature, varies from about one hour for light sections and small furnace charges of carbon or low-alloy tool steel, to about four hours for heavy sections and large furnace charges of high-alloy steel.

(e) Forging, normalizing and annealing temperatures of carbon tool steels are given as ranges because they vary with carbon content. The following temperatures are recommended:

Forging
0.60 to 1.25% C: the range given
1.25 to 1.40% C: the low side of the range

Normalizing
0.60 to 0.75% C: 1500 F
0.75 to 0.90% C: 1450 F
0.90 to 1.10% C: 1600 F
1.10 to 1.40% C: 1600 to 1800 F
For explanation, see Fig. 2, page 661.

Annealing
0.60 to 0.90% C: 1360 to 1400 F
0.90 to 1.40% C: 1400 to 1450 F

The Selection of Tool Steels

BY THE SUBCOMMITTEE ON TOOL STEEL

SIMPLIFICATION of the problems connected with the selection of tool steels has long been an aim of both producers and consumers. However, it is difficult to establish a workable yet simple set of rules which will serve as a solution to this problem. If it is to be complete, a tabulation of tools in common use and of recommended steels must be highly detailed and must include a large number of different tool steels for each application. As a result, such a tabulation loses much of its practical significance for the user. This article, therefore, will be restricted to a discussion of the general principles involved in selection and will include a tabulation of the metallurgical characteristics of the principal tool steel types, as an aid in selection. A correlation of these metallurgical characteristics with the requirements of the tool in operation should form the basis of a sound approach to the selection of a steel for any application.

Practical experience indicates that in the majority of instances the choice is not limited to a single type of tool steel or even to a particular family of tool steels for a workable solution to an individual tooling problem. Because it is desirable to select the steel that will give the most economical over-all performance, the tool life obtained with each steel under consideration should be judged by weighing such factors as expected productivity, ease of fabrication, and cost.

The majority of tool steel applications can be divided into a small number of groups or types of operations: cutting, shearing, forming, drawing, extrusion, rolling and battering. Cutting tools include drills, taps, broaches, hobs, lathe tools and the like. Shearing tools include shears, blanking and trimming dies, punches and such. Forming tools include forging dies, cold heading dies, die-casting dies. Battering tools include chisels and all forms of tools involving heavy shock. Many of these classifications can be further divided into cold working and hot working tools.

For each of these groups certain metallurgical characteristics are of utmost importance. Cutting tools must possess high hardness, high resistance to the softening effect of heat, and high wear resistance. Shearing tools require high wear resistance combined with fair toughness, and these characteristics must be properly balanced, depending on the tool design, thickness of the stock being sheared, and temperature of the shearing operation. Forming tools must possess high toughness and high strength and many require maximum resistance to heat softening. In battering tools high toughness is most important.

Hardness, strength, toughness, wear resistance and resistance to heat softening are, therefore, prime selective factors for tool steel applications. Many other properties must be seriously considered in individual applications; these include permissible distortion in hardening, permissible surface decarburization, hardenability or depth of hardness desired, resistance to heat checking, machinability and grindability, as well as heat treating requirements, including temperatures, atmospheres and equipment.

Table I is presented as an aid in the relative evaluation of these properties for the tool steels listed in the classification table on page 656 and discussed in the various articles on tool steel in this Handbook. The various tool steels have been combined into logical groups where possible, and the following properties have been rated as Good, Fair, or Poor: nondeforming properties, safety in hardening, toughness, resistance to softening effect of heat, wear resistance, machinability, and resistance to decarburization. Depth of hardening is rated as Shallow, Medium or Deep.

An attempt has been made to rate *all the steels in the table relative to one another,* rather than to rate them within any one particular class. All high speed steels have therefore been rated Poor in toughness, despite the fact that small differences exist in this property among the high speed steel types in question. These differences may be important when selecting a particular high speed steel for a cutting application. Similarly, the majority of the hot work steels have been rated as Good in resistance to the softening effect of heat; whereas significant differences exist in the "hot hardness" and "hot strength" of these types, requiring careful study when a steel must be selected for hot die work.

"Nondeforming" Properties. The first column in Table I rates the tool steels on the basis of the distortion normally obtained in hardening the respective grades from the normally recommended hardening temperatures. Unless otherwise specified, the quenching medium is the one that is standard for the grade. The steels of Class III and Steel VIJ are quenched either in oil or in water and a rating has been given for each type of quenching medium. This property is important in intricately designed tools which must maintain their shape after hardening. The steels rated Good or Best in this column can be machined very close to size prior to heat treatment so that little grinding will be required after the hardening operation. In general, water-hardening steels exhibit the most distortion and air-hardening steels exhibit the least. It is important to note, however, that carbon tool steels and other shallow-hardening types distort very little in heat treatment when the hardened case is small in comparison with the unhardened core for any particular tool or die design.

Safety in Hardening. The second column in Table I deals with the over-all freedom from heat treating difficulties which may be experienced in handling the tool steel grades in question. The ratings apply particularly to freedom from cracking when complicated or intricate sections are being hardened. It will be noted that the air- and oil-hardening steels prove superior to the water-hardening steels in this respect.

Toughness. The term "toughness", when applied to tool steels, is subject to several interpretations. In general, high-carbon steels will be found to have lower toughness than low-carbon steels. This is reflected in the good ratings given in the third column in Table I to the medium- and low-carbon tool steels of Classes III and IV. Carbon tool steels and other shallow-hardening steels which harden with a case and a core may, however, be rated Good in toughness, since the high compressive stresses existing at the surface enable them to withstand high tensile loads and repeated impact without early failure, regardless of the carbon content. The hardness of the tool itself will also have a considerable bearing on the toughness of the steel. The ratings given in Table I are based on use of the tool steels at their regular working hardness. In tool steels the concept of toughness is best expressed as the ability to resist breaking, rather than the ability to deform plastically before breaking, since most tools must be rigid articles which do not deform in service. Generally, slight plastic deformation renders these steels unfit for use.

Resistance to Softening Effect of Heat. This property, also called "hot hardness" or "red hardness", and reflected to some extent in the resistance of the material to tempering, is an important selective factor, especially for tools used for hot work. As the alloy content of the steel increases, especially in those alloying elements which form hard, stable carbides, the resistance to softening at elevated temperatures is improved. In the hot working tool steels of Class IV, rated Good to Very Good in Table I, the resistance to softening increases as the tungsten, chromium, molybdenum and vanadium contents increase. High speed steels have the best rating in this column.

Wear Resistance. Wear resistance, a property difficult to measure, increases as the carbon and alloy contents increase. A fair correlation can be made between the wear resistance of steels and their content of hard, undissolved carbide particles; other factors being equal, wear resistance is greatest in steels that have the most carbide particles. The hardness of the steels likewise affects the wear resistance markedly; the steels in Table I have been compared according to their behavior after hardening to the normal working hardness.

Machinability. The machinability ratings given are qualitative and are intended to show the relative difficulty

Table I. Approximate Comparison of Principal Types of Tool Steels on the Basis of Some Metallurgical Characteristics

Steel[a]	"Nondeforming" Properties[b]	Safety in Hardening[b]	Toughness	Resistance to Softening Effect of Heat	Wear Resistance	Machinability	Quenching Medium	Hardening Temperature Range[c] deg Fahr	Depth of Hardening	Resistance to Decarburization[d]

(a) These numbers are the ones used in the table of principal types of tool steels on page 656.

(b) See the article on "Composition and Heat Treatment of Nondeforming Tool Steels" (page 661). The letter "W" means "when quenched in water"; the letter "O", "when quenched in oil".

(c) The purpose of this column is to show the broad ranges of temperature employed in hardening. This information may serve to indicate the heat treating equipment required; it is not to be used as a specification. For more exact data on the hardening temperatures used for each type of steel, see the individual articles which follow in this Handbook (pages 660 to 676).

(d) Some steels decarburize much more than others on heating. This is important in many applications and has an influence on the type of heat treating equipment to be selected. This column is intended to show relative resistance to decarburization.

(e) Toughness decreases with increasing carbon content and depth of hardening.

(f) The lower carbon grades may be rated as Fair.

which might be experienced in machining the steels in question, during the manufacture of tools or dies. In addition to the hardness in the annealed condition, two factors affect the machinability of tool steels: (1) the quantity of hard excess carbides, which add wear resistance to the steels and decrease the life of the tools used to cut them, and (2) the microstructure of the steel itself, which is known to have a marked effect on certain machining operations. Low-carbon irons and stainless irons are very difficult to machine, presumably because of the preponderance of a soft ductile phase. Fine surface finish is difficult to achieve on tool steels of this nature.

Hardening Temperature Range. The hardening temperature ranges listed in Table I are necessarily very broad in most instances because of grouping several types of tool steels into one classification. For more accurate information on recommended hardening treatments the reader is referred to the individual articles covering the particular type of steel in question. The selection of tool steels may be influenced to some extent by the hardening temperature range, since this range must lie within the possibilities of the furnace equipment available. Resistance to decarburization, last column of Table I, will naturally be considered with the hardening temperature range.

Depth of Hardening. This column relates to the depth of hardening or hardenability of the individual tool steels. The hardenability ratings are given on the basis of the use of the particular quenching medium recommended in the previous column. Carbon tool steels in Class I and several of the carburizing grades in Class VI, as well as the tungsten finishing steel (Type VIK), are very shallow-hardening steels. These steels are generally quenched in water. The hardenability increases in tool steels as the alloy content increases, and for large tool or die sections it is imperative that a high-alloy steel be selected if high strength is to be developed throughout the section in the finished part.

Resistance to Decarburization. A study of this column is important in the selection of tool steels, since it influences the type of heat treating equipment to be selected, as well as the amount of material which should be removed from the surface after hardening. Both of these factors are important since they concern the economies of tool steel use. The ratings are intended to apply at the hardening temperature normally recommended. Those steels which are rated Poor must be protected in some way from decarburization during the heating cycle.

The Composition and Heat Treatment of Carbon Tool Steels

By the Subcommittee on Tool Steel

THIS article covers the processes to be followed in heat treating carbon tool steel for general purposes. For information regarding the heat treatment of specific types of tools, reference should be made to the articles in this Handbook on the particular tools in question.

Composition and Application. Carbon tool steel hardens with a hard case and tough core, except in small sizes. Sections smaller than about ½ in. will harden all the way through. Sections about $\frac{3}{32}$ in. will harden well in oil from 1500 F. (Hardenability testing of tool steels is discussed on page 412 of this Handbook.) For material such as drill rod and ground flat stock, oil quenching is often used to minimize distortion and secure greater safety in hardening.

By variation of the carbon content, a wide range of physical properties can be obtained. Increasing the carbon content increases hardenability, up to about 0.85% C. As the carbon content increases beyond 0.85%, its effect is to decrease hardenability. This is an important consideration in applications involving shock, such as cold header dies or tools operating under heavy pressure. A case that is too shallow may fail by sinking.

Types containing 0.20 to 0.75% Cr and others containing 0.20 to 0.50% V, while not carbon steels strictly speaking, are usually classed with the carbon tool steels.

Chromium in the range from 0.20 to 0.75% serves two functions. All other factors being equal, chromium-bearing carbon steels have greater depth of case and slightly more wear resistance than chromium-free steels of the same carbon content.

The addition of vanadium to carbon steels will decrease the depth of case and slightly increase toughness as compared with vanadium-free steels of the same carbon content; and will allow a wider hardening range with a wider range of case depths obtainable, and with little effect on grain size.

After a standardized heat treatment, case depth can be varied in steels of approximately the same composition, by variations in melting practice and prior treatment. This fact should not be confused with the influence of carbon content and of alloy additions, such as chromium and vanadium.

Table I. Approximate Chemical Compositions of Carbon Tool Steels[a]

Steel No.[b]	C	Mn	Si	Cr	V
IA	0.60 to 1.40	0.25	0.25	....	....
IB	0.60 to 1.40	0.25	0.25	0.20 to 0.75	....
IC	0.60 to 1.40	0.25	0.25	....	0.20 to 0.50

(a) The compositions given are type compositions only. Actual analyses of the steels they represent will vary a reasonable amount from these averages. It should be remembered that the more the composition of any steel varies from these averages, the more the treatment may differ from that recommended.

(b) These numbers are the ones used in the table of principle types of tool steels on page 656.

Lower carbon ranges are used for tools where toughness and resistance to shock are of primary importance; the higher carbon ranges are used where the main requirements are hardness, resistance to abrasion, or ability to hold a keen edge.

Thus, factors such as carbon content, alloy additions, melting practice and prior treatment have made available a class of steels with predetermined physical properties for a wide range of applications. Generally carbon steels are the easiest tool steels to machine and form. Frequently these steels are the only types that will serve successfully for specialized applications.

The type compositions are given in Table I. The ranges for the carbon content and a few of the more common applications for the steels listed are as follows:

Carbon Content, 0.60 to 0.75%. Hot forming or heading dies for short runs, machinery parts, hammers (sledges and pinch bars), concrete-breakers and rivet sets.

Carbon Content, 0.75 to 0.90%. Hot and cold sets, chisels, dies, shear blades, mining drill steel, smiths' tools, set hammers, swages and flatteners.

Carbon Content, 0.90 to 1.10%. Hand chisels, small shear blades, large taps, granite drill steel, trimming dies, drills, cutters, slotting and milling tools, mill picks, circular cutters, threading dies, cold header dies, jewelers' cold striking dies, blanking, forming and drawing dies and punches.

Carbon Content, 1.10 to 1.40%. Small cutters, small taps, drills, reamers, slotting and planing tools, wood-cutting tools, turning tools and razors.

Forging, Normalizing and Annealing. See table, page 657, and the article on page 653 of this Handbook.

Hardening. The steel should be heated uniformly to the temperature given in Table II and should be quenched in brine or water, preferably in a brine solution of 10% by weight, held at a temperature of 70 to 80 F. The tool should be removed from the bath while still warm, but not before it has cooled below 200 F.

The temperatures given in Table II are average for most tools. Small or intricate sections should be quenched from the lower side of the range. A fully hardened carbon steel

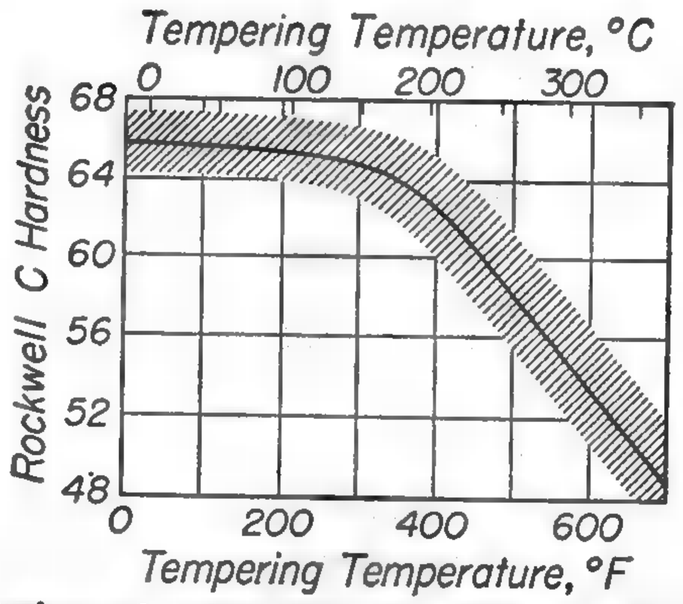

Fig. 1 Hardness of carbon tool steel containing 0.90% C or more, after quenching from the recommended temperature and tempering at 100 to 700 F

tool of 0.90% C or higher will have a Rockwell C hardness of 64 to 67, as shown in Fig. 1.

Tempering. After the steel has been quenched and allowed to cool below 150 F, it should be reheated to the tempering temperature, held for at least one hour, and then cooled in still air. The hardness resulting from tempering at these temperatures is shown in Fig. 1.

Suitable Tempering Temperatures for Various Tools. 300 to 375 F. Lathe tools and milling cutters for brass and copper alloys, scraper and cutting tools for soft metals, drawing mandrels and dies, bone-cutting tools, steel-engraving tools, gages, cutting tools for iron and steel, and threading dies for brass.

375 to 500 F. Hand taps and dies, hand reamers, drills, bits, cutting dies, penknives, milling cutters, chasers, inserted sawteeth, press dies for blanking and forming, rock

Table II. Hardening and Tempering Treatments for Carbon Tool Steels

Steel No.	Carbon, per cent	Rate of Heating for Hardening	Hardening Temperature, deg Fahr	Quenching Medium	Tempering Temperature, deg Fahr
IA, IB, IC	0.60 to 0.80	Slowly	1450 to 1550	Brine or water	300 to 650
IA, IB, IC	0.85 to 1.05	Slowly	1425 to 1550	Brine or water	300 to 650
IA, IB, IC	1.10 to 1.40	Slowly	1400 to 1525	Brine or water	300 to 650

drills, taps and dies, dental and surgical instruments, twist drills, hammer faces, wood-carving tools, forming dies, shear blades, reamers and hacksaws.

500 to 650 F. Bending dies, shear blades, chuck jaws, forging dies, drifts, tools for wood cutting, hammers and drop dies, axes, cold chisels, coppersmith tools, screwdrivers, molding and planing tools, hacksaws, butcher knives and saws.

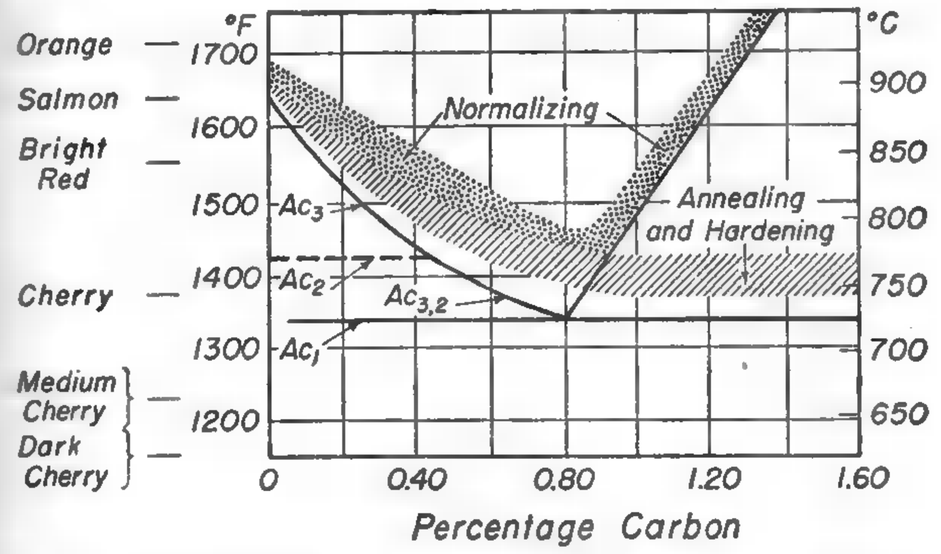

Fig. 2 Transformation temperature range for iron-carbon alloys, showing normalizing, annealing and hardening ranges

Notes About the Process. *Normalizing.* A normalizing treatment after forging and before annealing is recommended for all carbon tool steels to obtain a uniform and refined grain structure.

The proper normalizing ranges are shown in Fig. 2. Heating to temperatures much above the lowest which will give all austenite is conducive to austenitic grain growth and intergranular weakness.

A low normalizing temperature for high-carbon steels (1.25 to 1.50% C) fails to break up massive cementite and results in a brittle structure. The solubility of carbon in austenite increases with increasing temperature.

Quenching. The quenching temperatures given are average for most tools. Small or intricate sections should be quenched from the lower side of the range. However, some classes of tools, such as cold heading and cold striking dies, require higher temperatures.

The quenching temperature influences the hardness, hardenability and final grain size. Since these factors have marked effects upon the physical properties, uniformity of tool life cannot be obtained if the quenching temperature is not closely controlled. Since absolute uniformity of heating cannot be obtained, the best practice is to use temperatures about 50 to 75 F above Ac_1 (Fig. 2).

Brine or water is the usual quenching medium for carbon tool steels. For details concerning quenching, see the articles on pages 615 and 620.

Microstructure. The microstructure of the annealed steel should consist of carbide particles of a uniform and small size in a background of ferrite. Pearlite may be present in amounts less than 25%. The microstructure should be free from large carbide particles in network form. When tools are forged and subsequently normalized and annealed, full consideration should be given to producing the proper microstructure.

The Composition and Heat Treatment of "Nondeforming" Tool Steels

BY THE SUBCOMMITTEE ON TOOL STEEL

THIS article covers the heat treatment of the "nondeforming" types of tool steels, including the manganese oil-hardening, the tungsten oil-hardening, the chromium air-hardening, the manganese air-hardening, and the high-carbon high-chromium steels shown in Table I.

The word "nondeforming" is enclosed in quotation marks because no tool steel is absolutely nondeforming; during hardening, all steels change more or less in size and shape. The steels given in Table I deform less than other types of tool steel.

Application. These "nondeforming" steels are used for tools and dies having a design that prohibits the use of water-hardening steels because of the hazard of distortion or cracking during hardening. The oil-hardening steels (IIA and IIC) usually hold their dimensions less closely than the air-hardening steels (IIB and IID).

All the steels of this group are rather deep hardening and are often selected, where deep hardening offers an advantage, instead of carbon steels or other steels having shallow-hardening characteristics. In fully hardened small sections, these steels give approximately Rockwell C 63 to 65, but as the size of the section increases, the hardness decreases. This is particularly noticeable in steels of Group IIA.

The wear resistance of these "nondeforming" steels is roughly proportional to the amount of carbide present, and therefore is a function of both the carbon content and the alloy content. On this basis, steels IIC1 and IID3 have the greatest wear resistance, and steels IIA1, IIA2 the least. The chromium air-hardening steel IIB2 has wear resistance midway between the manganese oil-hardening grades (IIA1 and IIA2) and the high-carbon high-chromium steels, but at high hardness levels, chromium air-hardening steel has greater toughness than either of the others.

Selection among steels of the high-chromium type is generally on a basis of toughness, wear resistance and machinability. The 1.50% C type and the 1.00% C type are tougher and more readily machinable, but the 2.15% C type has better properties of wear resistance.

The steels in these groups, particularly the high-carbon high-chromium and the air-hardening steels, are well suited for tools, such as blanking, forming and trimming

Table I. Approximate Chemical Compositions of "Nondeforming" Tool Steels[a]

Steel No.[b]	C	Mn	Si	Cr	V	W	Mo	Co	Ni
IIA1	0.90	1.20	0.25	0.50	0.20 opt	0.50	....	....	....

(a) The compositions given are type compositions only. Actual analyses of the steels they represent will vary a reasonable amount from these averages. It should be remembered that the more the composition of any steel varies from these averages, the more the treatment may differ from that recommended.

"Opt" indicates that the element so marked is optional in the composition. Steels have been found satisfactory either with or without the element present.

(b) These numbers are the ones used in the table of principal types of tool steels on page 656.

dies, deep-drawing dies, wire-drawing dies, plug gages, burnishing broaches, thread-rolling dies, woodworking knives, shear blades and lathe centers.

Forging, Normalizing and Annealing. *See* table on page 657 and the article on page 653 of this Handbook.

Hardening. In order to hold distortion to a minimum and to secure maximum and uniform hardness, it is advisable to preheat slowly and uniformly to the temperatures indicated in Table II. This is recommended especially for the high-carbon high-chromium steels (IIC and IID) and for the chromium air-hardening steel IIB2, since the absorption of heat and the solution rate of the carbides are slower in these materials than in lower-alloy tool steels.

After being held at the preheating temperature for complete uniformity, the steel should be transferred to the hardening temperature shown in Table II. The actual temperature selected will depend on the mass, as will the holding time at this temperature prior to quenching. Steel IIA2 should be quenched as soon as uniformity has been obtained, while steels IIA1 and IIA3 may be held at temperature for ½ hr if desired. In steels IIA1 and IIA3 maximum hardness will result after soaking for up to ½ hr, but no soak should be given if minimum distortion is of greater importance. The holding time for the 5.00% or 12.00% Cr steels and the air-hardening manganese steel should be approximately twice as long as for carbon tool steel of similar size, but must be balanced against possible danger of decarburization.

The manganese oil-hardening, manganese air-hardening and tungsten oil-hardening grades are not particularly susceptible to decarburization and may be handled like carbon tool steels in hardening. Slightly oxidizing atmospheres are satisfactory. Salt baths or controlled-atmosphere furnaces are desirable but not necessary. The high-carbon high-chromium steels, however, partly because of the relatively high temperatures required for hardening, tend to decarburize and should be heated in a protective manner, by using salt baths, controlled-atmosphere furnaces or pack-hardening methods. This also applies to the 5.00% Cr air-hardening steel, IIB2; although with a somewhat lessened susceptibility to decarburization, small sections of this steel may be treated in semimuffle-type furnaces using a slight excess of fuel to air. When these chromium steels are to be pack-hardened, spent pitch coke is recommended, especially where edge strength is desired. Charcoal, which carburizes at the temperatures recommended, may be used where parts are required only to resist wear.

Attention should be called to the fact that large quantities of austenite may be retained after the high-carbon high-chromium steels or the 5.00% Cr air-hardening steel have been quenched from temperatures above those recommended in Table II. Low hardness (Fig. 1) may result, and in exceptional instances the steels are essentially nonmagnetic. Austenite retained in this way may produce secondary hardness since it transforms in subsequent tempering at about 1000 F. The high quenching temperature and the accompanying coarsened austenitic grain size may be of value in dies which must resist heat or in tools and dies which are to be nitrided after hardening. High-carbon high-chromium steels are readily nitrided either by the ammonia gas process or by tempering at 1000 F in cyanide bath mixtures.

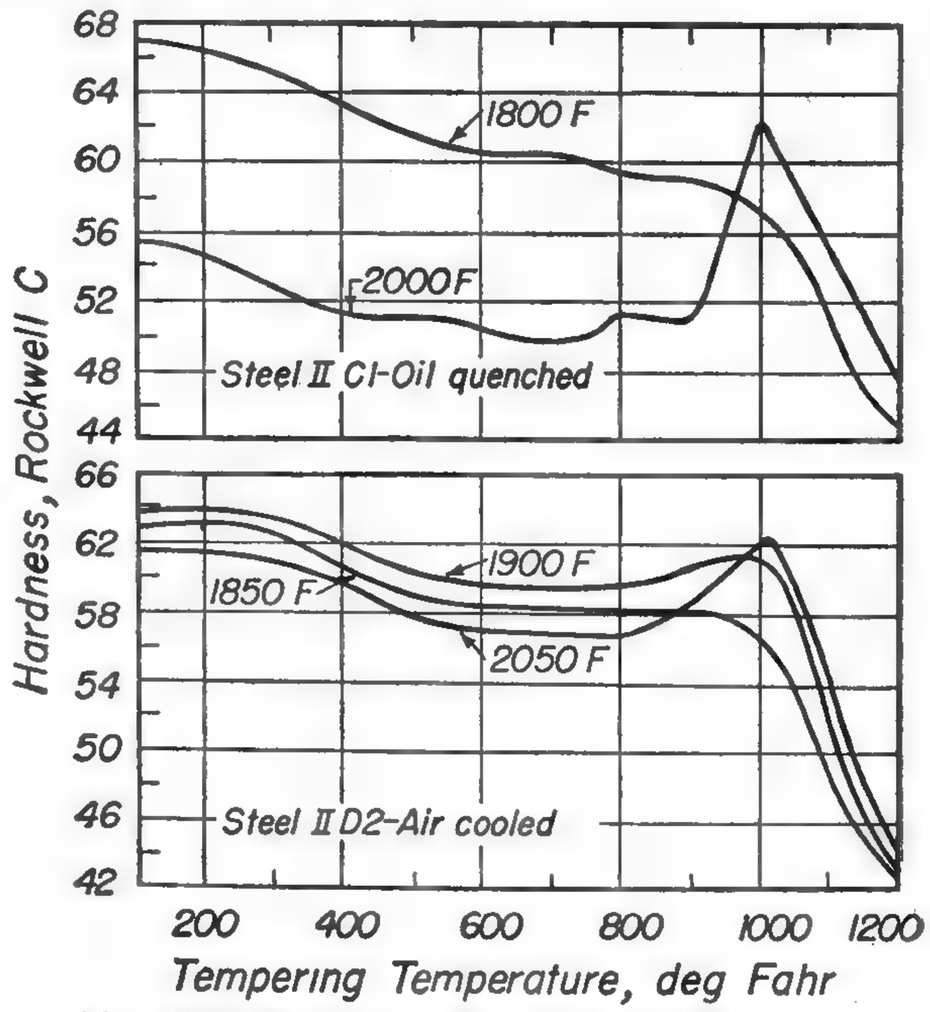

Fig. 1 Hardness and tempering curves for high-carbon high-chromium steels.

Tempering. These steels should be reheated slowly to the desired tempering temperature in order to prevent cracking. Tempering of the high-carbon high-chromium steels below 350 F is rarely advisable on account of the lack of toughness that results. Because of the possible large variation in composition from the averages shown in Table I, the user should consult published information on the particular steel in question, for determining the relation between hardness and tempering temperature.

Notes About the Process. For the oil-hardening steels listed, it is important to avoid heating the quenching oil to a temperature approaching the flash point, during prolonged and continuous quenching. The best oil temperature is generally 100 to 150 F. The ratio of bath volume to mass of steel is an important factor.

The edges and corners of any piece of steel harden more readily than large flat areas because of the difference in the rate of heat extraction. This is particularly noticeable with large flat sections of the IIA steels of Table I. In order to crack off the scale and harden the broad flat surface properly, it is advisable to force plenty of oil against this surface, ordinarily by means of a pump under good pressure, and to use the higher side of the hardening range.

Table II. Hardening and Tempering Treatments for "Nondeforming" Tool Steels

Steel No.	Preheat Temperature, deg Fahr	Rate of Heating for Hardening	Hardening Temperature, deg Fahr	Time at Temperature, minutes	Quenching Medium	Tempering Temperature, deg Fahr
IIA1	1200	Slowly	1450 to 1500	30[a]	Oil	325 to 500
IIA2	1200	Slowly	1400 to 1475	Do not soak	Oil	325 to 500
IIA3	1200	Slowly	1575 to 1625	30[a]	Oil	350 to 550
IIB1	1250	Slowly	1450 to 1600	15 to 30	Air	300 to 500
IIB2	1450	Slowly	1700 to 1800	15 to 30	Air	350 to 1000[b]
IIC1	1500	Very Slowly	1750 to 1825	15 to 45	Oil	350 to 1000[b]
IID1	1500	Very Slowly	1775 to 1850	15 to 45	Air	350 to 1000[b]
IID2	1500	Very Slowly	1800 to 1900	15 to 45	Air	350 to 1000[b]
IID3	1500	Very Slowly	1900 to 1975	15 to 45	Air	350 to 1000[b]

(a) Soak 30 minutes for maximum hardness. Do not soak for minimum distortion.
(b) The higher tempering temperatures are used when the quenching temperature is high. It is sometimes considered undesirable to temper these steels between 600 and 800 F.

High-carbon high-chromium steels may fail differently from low-alloy or carbon tool steels. Where the latter steels generally require regrinding because of becoming dull, the high-carbon high-chromium steels may wear so long that deep chipping of the edges results from fatigue. More frequent sharpening of such tools will be beneficial in preventing this type of failure. In redressing tools or dies after such failure, it is advisable to anneal, remachine and reharden, rather than resort to grinding.

Grinding of the high-carbon high-chromium steels in the hardened condition is difficult because of their high resistance to abrasion. Unless proper grinding wheels are used, heat checks may form. Soft wheels of self-dressing character are recommended.

The so-called "martempering" treatment, involving quenching in a bath at 250 to 400 F, has been applied successfully to oil-hardening tool steels, with consequent reduction in distortion and cracking.

The Composition and Heat Treatment of Shock-Resisting Tool Steels

BY THE SUBCOMMITTEE ON TOOL STEEL

THE tool steels used for industrial applications in which resistance to shock is of prime importance are of the medium-alloy type and include the chromium-vanadium, the low silicon-manganese, the high silicon-manganese and the chromium-tungsten steels, although the plain carbon steels with 0.80 to 0.90% C are also used. The nominal compositions of these steels are given in Table I.

Table I. Approximate Chemical Compositions of Shock-Resisting Tool Steels[a]

Steel No.[b]	C	Mn	Si	Cr	V	W	Mo
IA	0.80 to 0.90	0.25	0.25	....	....	....	....
IC	0.80 to 0.90	0.25	0.25	....	0.20 to 0.50	....	....
IIIA	0.50	0.60	0.25	1.00	0.20	....	....
IIIB	0.55	0.40	1.00	....	0.25 opt	....	0.50
IIIC	0.55	0.80	2.00	0.30 opt	0.25 opt	....	0.40 opt
IIID	0.55	0.25	0.25	1.25	0.25 opt	2.50	0.50 opt
IIIE	0.55	0.25	1.00	1.25	0.25 opt	2.50	0.50 opt

(a) The compositions given are type compositions only. Actual analyses of the steels they represent will vary a reasonable amount from these averages. It should be remembered that the more the composition of any steel varies from these averages, the more the treatment may differ from that recommended.

"Opt" indicates that the element so marked is optional in the composition. Steels have been found satisfactory either with or without the element present.

(b) These numbers are the ones used in the table of principal types of tool steels on page 656.

Application. Shock-resisting steels are generally used for pneumatic chisels and calking tools, rivet busters, concrete breakers, track chisels, punches, rivet sets, and other tools requiring a tough hard steel having good fatigue resistance. Steels IIIA, IIIB and IIIC may also be used successfully for hand chisels, beading tools, flue expanders, nail sets, screw drivers, drift pins, sledges and other tools requiring a steel hard enough to resist spalling, upsetting or galling.

Forging, Normalizing and Annealing. *See* table, page 657, and the article on page 653 of this Handbook.

Hardening and Tempering. The temperatures and quenching mediums to be used in the hardening and tempering of these steels are given in Table II. In determining the portion of the quenching temperature range to be used in the hardening treatment, consideration should be given to the size (cross-sectional area) of the tool and to the as-quenched hardness desired. Generally the quenching temperature is increased as the size of the tool increases or as it is desired to produce higher as-quenched hardness. All steels should be tempered within the range given in Table II to obtain the desired hardness. Ordinarily, tools of higher hardness that have been tempered in the lower portion of the tempering temperature range will exhibit greater resistance to wear, abrasion, galling and upsetting, with a sacrifice of toughness; while those of lower hardness, tempered at higher temperatures within the range, will be tougher, with a sacrifice of wear resistance but with less tendency to spall, chip and break.

Table II. Hardening and Tempering Treatments for Shock-Resisting Tool Steels

Steel No.	Hardening Temperature,[a] deg Fahr	Quenching Medium	Tempering Temperature, deg Fahr	Hardness, Rockwell C
IA, IC	1425 to 1475	Brine or Water	400 to 700	62 to 48
	1500 to 1550	Brine or Water	300 to 800	60 to 50
IIIA	1600 to 1700	Oil	300 to 800	55 to 45
IIIB	1550 to 1600	Brine or Water	300 to 800	60 to 52
	1550 to 1650	Brine or Water	300 to 800	60 to 50
IIIC	1600 to 1700	Oil	300 to 800	58 to 50
IIID	1700 to 1800	Oil	400 to 1000	58 to 50
IIIE	1700 to 1800	Oil	400 to 1000	58 to 48

(a) Soaking at the hardening temperature should be avoided except for steels IIID and IIIE. Large tools or tools in which decarburization may be harmful should be preheated.

Double heat treating procedures are occasionally used to develop different properties in different parts of a tool. Chisels may be hardened all over in oil and then tempered at 800 to 900 F to a hardness of approximately Rockwell C 42 to 50, after which the cutting edge only is heated to the hardening temperature, quenched in brine or water and tempered, as indicated in Table II. By this method, maximum resistance to spalling is developed in the chisel shank and maximum hardness is obtained at the cutting edge.

Some types of tools may be either differentially heated in liquid baths or differentially quenched in fixtures. Such treatments cause a gradation of hardness and a combination of resistance to cutting, galling, abrasion, shock, upsetting and spalling. Rivet sets, for example, may be held in a fixture and quenched, shank end down, in a vertically rising stream of water. This will produce a differential rate of cooling between the shank end and the head end. As a result, the shank will have high hardness to withstand upsetting and the head, lower hardness to resist spalling.

The Composition and Heat Treatment of High Speed Steel Cutting Tools

BY THE SUBCOMMITTEE ON TOOL STEEL

THIS article covers the heat treatment of molybdenum and tungsten high speed steels as listed under Group V of the tool steel classification table on page 656. The composition types are repeated here in Table I.

Molybdenum High Speed Steels

Application. The first three steels of Group VA in Table I can be classified as general-purpose steels for average tool application under normal operating conditions. Steel VA4, an alloy highly resistant to abrasion, is ideally suited for light cuts or for machining abrasive materials. The molybdenum-cobalt steels listed under Group VB in Table I are special-purpose alloys for uses requiring high hardness at elevated temperatures ("red hardness"), particularly for cutting hard, gritty or scaly material such as hard cast alloys and heat treated steels.

Forging. All these steels are forgeable but they must be

heated carefully to prevent excessive decarburization during the heating cycle. This is particularly true with types VA1, VA2 and the cobalt grades. They should all be heated slowly to a uniform temperature of about 1500 F in a slightly oxidizing atmosphere, before being heated to the forging temperatures recommended on page 657. These steels, particularly VA1, VA2 and the cobalt series, can be protected from excessive decarburization by coating with borax (*see* below). After forging, all pieces should be slowly cooled to at least 300 F either by cooling in the furnace or by burying in silocel, lime, mica or dry sand before annealing.

Table I. Approximate Chemical Compositions of High Speed Tool Steels[a]

Steel No.[b]	C	Mn	Si	Cr	V	W	Mo	Co
VA1	0.85	0.30	0.25	4.00	2.00	....	8.00	....
VA2	0.80	0.30	0.25	4.00	1.00	1.50	8.50	....
VA3	0.85	0.30	0.25	4.00	2.00	6.25	5.00	....
VA4	1.20	0.30	0.25	4.00	4.00	6.00	4.50	....
VB1	0.85	0.30	0.25	4.00	1.00	1.50	8.50	5.00
VB2	0.85	0.30	0.25	4.00	2.00	1.50	8.50	8.00
VB3	0.85	0.30	0.25	4.00	2.00	6.25	5.00	5.00
VB4	0.85	0.30	0.25	4.00	2.00	6.25	5.00	8.00
VC1	0.70	0.30	0.25	4.00	1.00	18.00	....	....
VC2	0.85	0.30	0.25	4.00	2.00	18.00	0.75	....
VC3	1.00	0.30	0.25	4.00	3.00	18.00	....	....
VD1	0.80	0.30	0.25	4.00	2.00	14.00	0.75	5.00
VD2	0.75	0.30	0.25	4.00	1.00	18.00	0.75	5.00
VD3	0.80	0.30	0.25	4.00	2.00	18.00	0.75	9.00
VD4	0.80	0.30	0.25	4.00	2.00	20.00	0.75	12.00

(a) The compositions given are type compositions only. Actual analyses of the steels they represent will vary a reasonable amount from these averages. It should be remembered that the more the composition of any steel varies from these averages, the more the treatment may differ from that recommended.

(b) These numbers are the ones used in the table of principal types of tool steels on page 656.

Annealing. These steels must be fully annealed after forging or when rehardening is required. Pack annealing in tightly closed containers is recommended to decrease the amount of decarburization. The packing material can be dry sand or lime to which a small amount of charcoal has been added; burned cast-iron chips are also satisfactory. The container should be filled in such a way with the steel to be annealed that a minimum amount of packing material is required, since this material acts to insulate the box and will slow down the heating cycle. After the steel has reached the temperature specified, it should be held at temperature, as recommended in the table on page 657, depending on the size and weight of the boxes or pipe; and should then be slowly cooled in the furnace at a rate not exceeding 50 °F per hr, until a temperature of 1200 F is reached, when a faster rate of cooling is permissible.

Hardening. During the hardening of molybdenum high speed steels necessary precautions should be taken to minimize decarburization. Salt baths are excellent for hardening these steels but since, for efficiency, salt baths should be operated continuously, they are not practical unless large quantities of tools are to be hardened (*see* article on "Salt Baths", page 283). For intermittent hardening, controlled-atmosphere furnaces will produce satisfactory results if proper atmospheres are maintained, or if the tools are coated with borax or copper paint (*see* Notes about the Process, below).

Preheating. Preheat the tools uniformly to between 1350 and 1500 F in a semimuffle or controlled-temperature furnace or to between 1500 and 1550 F in a salt bath. For very large tools, a good practice is to use a double preheating by keeping one furnace at 1000 to 1100 F and the second furnace at 1500 to 1550 F. Some preheating salts have such a high melting point that, to keep the high-temperature furnace running continuously, a double preheating setup is required because of the thick layer of salt that freezes on the work. A preheating salt with a lower melting point will eliminate this condition.

Heating for Hardening. After thorough preheating, the tools should be placed quickly in the high-temperature furnace or salt bath, operating at a temperature within the range given in Table II. In controlled-atmosphere furnaces with reducing atmospheres, the heat transfer is rather slow, particularly at these temperatures, so the tools will come to temperature much more slowly and, for obtaining suitable solution of carbides, will require a longer time at temperature than is necessary in salt baths. For comparable results, tools can be heated in a salt bath at a somewhat lower temperature.

Table II. Hardening and Tempering Treatments for Molybdenum High Speed Steels

Steel No.	Hardening Temperature,[a] deg Fahr
VA1	2150 to 2225
VA2	2150 to 2225
VA3	2200 to 2275
VA4	2200 to 2250
VB1	2200 to 2250
VB2	2200 to 2250
VB3	2200 to 2250
VB4	2200 to 2275

(a) Heating for hardening should follow preheating at 1350 to 1550 F. When the high-temperature heating is carried out in a salt bath, the temperature should be about 25 F lower than those given in this table.

Quenching Medium. Oil, air or molten bath.

Tempering Temperature. 1000 to 1150 F.

Quenching. These steels can be quenched in air, oil or a molten bath. Except for thin tools, air-quenched between plates to keep them straight, it is customary to quench in oil from muffle or semimuffle furnaces and in molten salt from a high-temperature salt bath. After its temperature has been equalized in the salt quench, the tool is air-cooled. To minimize quenching strains and prevent cracking of large cutters hardened from furnace, an interrupted oil quench is often used, wherein the cutter is cooled in the oil until just when it loses color (about 1000 F); then it is cooled in air. All tools should be cooled sufficiently for handling without gloves, after which they should be tempered immediately.

Straightening. When straightening is required, it should be done immediately after quenching, while the tool is between 800 and 400 F. Tools can be kept in this range with a torch and then cooled in air before tempering.

Tempering. After hardening (and straightening, if necessary) the tools should be placed in the tempering furnace or salt bath, as soon as they can be held with bare hands. There they should be reheated to a temperature within the range specified in Table II and should be held at temperature a minimum of 2 hr. Then they should be cooled in air until they can be handled again, and the same cycle is repeated. This double tempering is recommended to obtain maximum toughness along with the hardness produced by the treatment.

Tungsten High Speed Steels

Application. Steel VC1 is the general-purpose 18–4–1 type of high speed steel, steel VC2 is the 18–4–2 type and VC3 is the 18–4–3 type. The higher vanadium contents of the VC2 and VC3 steels make them more resistant to wear and abrasion and ideal for cutters taking fine cuts, such as broaches and reamers. The tungsten-cobalt steels listed in Group VD are all special-purpose steels for use where conditions require high "red hardness" and resistance to abrasion. The cobalt series steels are more brittle than those not containing this element; therefore they are not recommended for fine-edged tools or tools for finishing cuts. Cobalt tool steels are used in tools for heavy-duty operations, such as lathe tools and cutters for heavy cuts.

Forging and Annealing. See discussion of molybdenum high speed steels, above.

Hardening. Since the tungsten high speed steels are more resistant than the molybdenum steels to decarburization during hardening, they can be successfully hardened in a wider range of furnaces, but controlled-atmosphere furnaces or salt baths are considered best. Because high temperatures are required for hardening the tungsten-

cobalt types, and because cobalt will diffuse from the surface, a reducing atmosphere or salt bath is recommended.

Preheating. All tools should be preheated thoroughly and uniformly to within the temperature range given in Table III. It is advisable to use a double preheating for very large cutters with gashes or sharp angles at the base of the teeth. When the tool has been thoroughly heated in a furnace that is being held at 1100 to 1200 F, it is then placed in the second furnace, operating at the higher temperatures given in Table III.

Table III. Hardening and Tempering Treatments for Tungsten High Speed Steels

Steel No.	Hardening Temperature,(a) deg Fahr
WC1	2300 to 2375
WC2	2325 to 2375
WC3	2250 to 2325
WD1	2325 to 2375
WD2	2350 to 2400
WD3	2350 to 2400
WD4	2350 to 2400

(a) Heating for hardening should follow preheating at 1500 to 1600 F. When the high-temperature heating is carried out in a salt bath, the temperatures should be about 50 F lower than those given in this table.

Quenching Medium. Oil, air or molten bath.

Tempering Temperature. 1000 to 1100 F.

Heating for Hardening. After thorough preheating, the tools should be placed quickly in the high-temperature furnace or salt bath, operating at a temperature within the range given in Table III. Because of the higher temperatures and the leaner atmospheres used, tools made of tungsten high speed steels will come to temperature faster and will require slightly less time at temperature than tools made of the molybdenum steels. The tools should not be kept at the high temperature long enough to cause excessive grain growth or heavy scaling of the surface. For comparable results, salt bath hardening can be done at a somewhat lower temperature.

Quenching, Straightening and Tempering. See discussion of molybdenum high speed steels, above.

Surface Treatments of High Speed Steel Tools

In some tool applications the development of an extremely hard surface on the tool is advantageous, particularly for light cutting, as in reaming, or for machining material of an abrasive nature, such as aluminum, copper, cast iron, hard rubber or plastics. A hard skin effect can be produced by treating the finished tool in a cyanide bath (a salt mixture containing about 28 to 30% cyanide and having a low melting point). This treatment is carried out by preheating the tools to 800 or 900 F, immersing them in the casing salt bath operating at 1000 to 1050 F, and leaving them there for a length of time determined by the size and nature of the tool being treated. A tool is seldom treated for more than an hour, which is enough time to produce a case depth of approximately 0.001 in. Because this surface case is inherently brittle, more delicate tools are immersed for shorter periods. For example, small drills and taps of fine pitch may require only 10 or 15 min treatment, whereas a larger tool may take an hour to develop sufficient case for obtaining the desired results. After the tools have cooled to room temperature, the adhering salt is washed off in hot water. (*See also* the article "Salt Baths", page 283.)

Although many tools are used as treated in the cyanide bath, it has been recommended by some to retemper at 950 to 1000 F for an hour, in order to toughen the case without affecting its hardness. This should be done in a tempering salt bath so that no heavy oxide is produced.

Another surface treatment used for both cased and uncased tools, after the final grinding operation, is tempering in a salt bath to produce a surface film of iron oxide, or tempering in steam in a furnace, giving similar results and a blue color to the surface. The oxide film is supposed to be porous, so cutting oil will be absorbed and will present a lubricated surface to the chip.

Notes About the Process

Protection of Surfaces During Heating (Other Than by Salt Bath). Because of the tendency of molybdenum high speed steels to decarburize when heated to the forging or hardening temperature range, the use of a borax film or proper furnace atmosphere is helpful in minimizing decarburization. Borax may be lightly sprinkled over the steel at a low temperature (1000 to 1400 F). When reheating is necessary during forging, more borax should be applied. Small tools, heated as above, can be rolled in a box of borax.

A method more suitable for finished tools is to apply the borax in the form of a saturated water solution. The unheated tools can be immersed in the solution at 180 to 212 F, or the solution can be applied with a brush or spray. Pieces so treated are heated as usual; care must be taken not to scrape off the borax during the handling.

When borax is used in a furnace with a Carborundum bottom, it is necessary to use a metal pan, preferably of stainless iron, to prevent the borax from fusing with the Carborundum. Such fusion produces a glasslike insoluble coating impossible to remove from a tool without damage to the cutting edge.

Another method of protecting finished tools for hardening is to apply a coating of copper paint which can be brushed or sprayed on. After drying, a protective coating of copper is left on the tool.

Controlled-Atmosphere Furnaces. Controlled-atmosphere furnaces can be used successfully if care is taken to maintain an atmosphere that is neutral in chemical reactions with the surface of the steel. Both electric and fuel-heated furnaces are available in which the atmosphere is independent of the source of heat. Some furnaces have a built-in combustion chamber, wherein the products of combustion of gas and air are circulated through a drying system to eliminate water vapor, and are then returned to the hardening chamber for protecting the work. A second type of furnace is designed with an inner retort, which is heated to the furnace temperature. The retort is filled with charcoal, and air is passed through. The charcoal burns, producing a gas high in carbon monoxide, which is used as a protecting atmosphere. Other furnaces are made with special external gas-making units, whence the prepared gas is pumped into the furnace for controlling decarburization. Most of these furnace atmospheres are high in carbon monoxide so that a carburizing reaction can take place.

Another method for producing an atmosphere that will protect the surface is to heat the tools in a block or muffle of suitable carbonaceous material, wherein an atmosphere high in carbon monoxide is generated at the hardening temperature. However, the size of the muffle is limited, so this method is adapted only to small tools.

Salt Baths. For tools that cannot be ground after hardening, or for tools that require the best possible surface condition and edges kept sharp, salt bath heating will give the best results. The only appreciable change in dimensions will be expansion or contraction caused in quenching the tool or caused by the change in structure of the steel while hardening. Three salt baths are generally used—the preheating, high-temperature, and quenching baths. The function of the quenching bath is to equalize the temperature as well as to assure a clean surface after heat treatment. A discussion of the composition and use of salt baths is given in the article on page 283 of this Handbook.

The Composition and Heat Treatment of Die Blocks and Hot Die Inserts

By the Subcommittee on Tool Steel

THIS article covers the processes to be followed in the heat treatment of die blocks and die inserts generally used in forging hammers and presses.

Many users purchase die blocks in the heat treated or prehardened condition, ready for the sinking of the initial impression. Subsequent resinking and service may be had without annealing or rehardening the dies after each operating service. This applies to dies of commercially machinable hardness. Such die blocks are usually furnished with a uniformity of five points of scleroscope hardness and in a range of 40 to 60 scleroscope (265 to 426 Brinell). Ordinarily, the shallower the impression, the greater is the hardness. Users can also purchase prehardened die blocks of specially treated, free-machining steel, in a range of 60 to 70 scleroscope hardness (426 to 514 Brinell) with only moderately increased machining resistance.

Composition. The approximate chemical compositions of carbon and alloy steels generally used in die blocks and die inserts are given in Table I.

Forging, Normalizing and Annealing. In heating for forging, normalizing and annealing, the steel should be brought slowly and uniformly to the temperature given in the table on page 657. Steels VIF2 and VIF3 should be cooled very slowly between 900 and 600 F.

Hardening. The die block should be warmed in front of the furnace to remove the chill, then charged into the furnace at not more than 500 F. Heating for hardening should be slow and uniform at a rate of approximately 150 to 250 °F per hr, depending on the size. The greater the size, the slower should be the rate of heating; also, the more highly alloyed the steel, the slower should be the heating. The time for holding at temperature should be approximately ¼ hr for carbon steels and ½ hr for alloy steels per inch of average cross-sectional dimension. The hardening temperatures are given in Table II.

Carbon steel die blocks are usually quenched in water (60 to 70 F) or, under certain conditions, in brine, and should be completely immersed, face down, for ½ to 2 min, depending on size. Then the shank is withdrawn until the block is immersed to a depth of 1 to 1½ in. below the deepest impression. To develop full hardness, a geyser of ample volume should be directed against the center of the die impression. The face of the die block should be cooled to 400 F, or to a point where reheating from the inside is not likely to occur to a sufficient degree to cause softening.

Die blocks that require oil quenching are entirely immersed in an oil bath (100 to 150 F) circulated to give maximum heat dissipation. The volume of the oil bath should be sufficient to keep it at proper temperature for uniform results. When large die blocks are being quenched, a strong geyser should be directed toward the center of the impression to insure a uniformly high hardness. The die blocks should be held beneath the surface of the oil until they have cooled to approximately 400 F.

Tempering. After quenching in oil, water or brine, the die blocks should not be allowed to stand in the as-quenched condition, but should be placed immediately in a suitable furnace or bath or on a hot plate (shank down), and should be equalized and heated slowly and uniformly to the desired tempering temperature, as given in Table II. Die blocks should be charged into a furnace or bath maintained at 400 F, and never above 500 F. The rate of heating to the tempering temperature should be the same as for hardening; when the die block is of intricate design or the thickness is very uneven, a slower rate is suggested in order to heat the heavy sections with a minimum of temperature difference between the thinnest and thickest portions. The time at temperature should be about:

¾ hr per in. of average thickness—up to 8 in.—but in no instance less than 2 hr.
⅞ hr per in. of average thickness—8 to 10 in.
1 hr per in. of average thickness—more than 10 in.

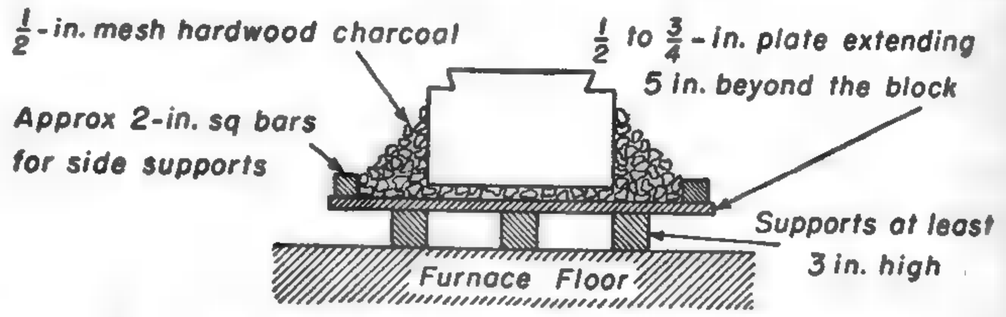

Fig. 1 Method of protecting surface of die block during heating for hardening

The dies should be cooled in still air from the tempering temperature.

Die-Block Inserts. The term "insert" may refer to a die block used to form the entire forging. It frequently has less thickness than a regular die block, because it is held in a die-block holder. On the other hand, "inserts" usually refers to the small sections set in a die block to strengthen or minimize the wear at one or more points in the die-block impression. These inserts are generally made from a more expensive die steel and will last as long as the other portions of the impression, thus considerably improving the life of the die block.

Hot die steel inserts may be made from a variety of types of steel; the more common steels used are listed in Table I and the heat treatments in Table II.

Notes About the Process. *Protection of Surface of Die Blocks When Heating for Hardening.* To reduce scaling

(a) When die is to be used for cold work.
(b) When die is to be used for hot work.
(c) Composition, size, time at tempering temperature and other processing variations tend to give slight variations in resulting hardness.
(d) The hardness values given result from the use of a quenching temperature of 2100 F. When greater toughness is desired, use 2000 F quenching temperature. This results in Brinell impression diameters 0.05 to 0.10 mm larger than those corresponding to the Brinell hardness numbers given. When higher hardness is desired, quench from 2200 F. This will result in a sacrifice of toughness and will give Brinell impression diameters 0.05 to 0.10 mm smaller than those corresponding to the Brinell hardness numbers given in this table.

and decarburization of the impression, it is recommended that die blocks and inserts be heated in a controlled-atmosphere furnace or with the impression placed face down in charcoal or packed in spent pitch coke (Fig. 1).

Air-Blast Hardening. When die blocks or inserts are hardened in air, the blast must be dry and so directed as to strike the impression face uniformly. An air pressure of 12 to 24 oz with ample volume is suggested.

Tempering. Carbon steel die blocks are sometimes tempered on a hot plate. The die block is placed shank down on the hot plate and heated until the desired color or scleroscope hardness is obtained on the face. When hot die blocks are tested with the scleroscope, the readings will be 4 to 5 points lower than in testing subsequently at room temperature. Accordingly, proper allowance must be made to insure final desired hardness. When relying on temper color to indicate hardness, the following is suggested as a guide: faint straw, 400 F; straw, 440 F; deep straw, 475 F; bronze, 520 F; peacock, 540 F; full blue, 590 F; light blue, 640 F.

The Composition and Heat Treatment of Tools for Hot Forging Machines

By the Subcommittee on Tool Steel

THE composition and heat treatment of steels used for tools in hot forging machines (gripper dies, header dies, piercers, crowners, punches and such) depend on the conditions and operating temperatures encountered in actual service.

Hot forging machine operations usually require tools having a combination of the following characteristics:

1 Resistance to wear and to washing at elevated temperatures, that is, "red hardness"
2 Resistance to "heat checking"
3 Resistance to softening from repeated or continuous heating at elevated temperatures, that is, "thermal stability"
4 Sufficient toughness to prevent breakage.

The compositions of steels commonly used as tools for hot forging machines are given in Table I.

These steels may be divided into three groups in accordance with their alloy contents.

Group I. Low-Alloy Steels (Steels VIF3 and IIIE). Used for short runs and general applications where operating temperatures are not very high and where "red hardness" and high thermal stability are, therefore, not the chief requisites. As a group, these steels have high toughness and water cooling is permissible.

Group II. Medium-Alloy Steels (Steels IVA2, IVB and IVC). This group of steels includes primarily either straight chromium steels or chromium steels with additions of silicon, tungsten or molybdenum.

These steels are probably the most widely used for general hot working applications where operating temperatures are not excessively high and where rapid cooling of the working surfaces may be encountered. Steels of this group have good toughness and may be water-cooled in service.

Group III. High-Alloy Steels (Steels IVD, IVF1, IVF2 and IVE1). These steels contain substantial amounts of tungsten or molybdenum or both. They are useful under high-temperature operating conditions requiring maximum "red hardness" and resistance to softening. Water cooling is generally not recommended.

Forging and Annealing. The recommendations for forging and annealing are given in the table on page 657 and in the article on page 653.

Table I. Approximate Compositions of Steels for Tools for Hot Forging Machines[a]

Steel No.[b]	C	Mn	Si	Cr	V	W	Mo	Ni
VIF3	0.55	0.60	0.85	1.00	0.10 opt	....	0.75	2.00
IIIE	0.55	0.25	1.00	1.25	0.25 opt	2.50	0.50 opt	....
IVA2	0.90	0.30	0.30	4.00	0.75 opt	....	0.50 opt	....
IVB	0.35	0.30	1.00	5.00	0.40 opt	1.25 opt	1.50	....
IVC	0.40	0.30	1.00	5.00	0.40 opt	5.00	....	....
IVD	0.45	0.60	1.50	7.50	0.40 opt	7.50	....	....
IVF1	0.30	0.25	0.25	3.50	0.50 opt	9.00	....	....
IVF2	0.40	0.25	0.25	2.50	0.50	12.00	....	....
IVE1	0.40	0.25	0.50	3.75	0.75	1.00	5.75	....

(a) The compositions given are type compositions only. Actual analyses of the steels they represent will vary a reasonable amount from these averages. It should be remembered that the more the composition of any steel varies from the average, the more the treatment may differ from that recommended.

"Opt" indicates that the element so marked is optional in the composition. Steels have been found satisfactory either with or without the element present.

(b) These numbers are the ones given in the table of principal types of tool steels on page 656.

Hardening and Tempering. Temperatures for hardening and tempering are given in Table II. The usual precautions should be taken to avoid carburization, decarburization or excessive scaling. The soaking time at the specified hardening temperature depends on the size of the tool as well as on the available heat treating equipment. The tempering temperature to be used depends on the hardness desired. The tempering should continue at least 3 to 4 hr. Rather large tools should be held at temperature for a minimum of 1 hr per in. of thickness.

Whenever possible, the surface oxide remaining after heat treatment should be left on the tools unless scaling has been excessive. Such an oxide on the surface retards seizing and galling. If grinding or polishing exposes bare metal, it is recommended that the tools be reoxidized at a temperature about 50 F below the tempering temperature. About 30 min at temperature is all that is required for this operation.

The usual working hardnesses of these steels in various applications are shown in Table III.

Table II. Hardening and Tempering Treatments for Tools for Hot Forging Machines

Steel No.	Preheat Temperature, deg Fahr	Hardening Temperature, deg Fahr	Quenching Medium	Tempering Temperature, deg Fahr
VIF3	1250	1525 to 1575	Oil	900 to 1125
VIF3	1250	1625 to 1675	Air blast	800 to 1100

IVB, IVF1, IVF2, IVD, IVE1	Piercers	43 to 48
IIIE, IVB	Crowners	40 to 45
IVD, IVF2	Cutoff tools	45 to 50
IVB, IVF1, IVF2, IVE1	Nut dies	43 to 48

The Composition and Heat Treatment of Tools for Hot and Cold Trimming

BY THE SUBCOMMITTEE ON TOOL STEEL

TOOLS for hot and cold trimming include punches and dies used in removing the flash from forgings. The chemical composition of trimming-tool steels generally depends on the type of trimming operation, the mass of the forging involved, the thickness of the flash, the trimming temperature, the chemical composition and hardness of the material trimmed, and the amount of production expected. When trimming is done hot, "red hardness" of the tool is required in addition to resistance to abrasion from the scale present. Compositions of steels for trimming tools are given in Table I.

Cold trimming usually involves severely abrasive conditions and requires tools sufficiently tough not to break or chip. Toughness is secured by placing tools in service at intermediate hardness ranges (Rockwell C 52 to 60).

Punches and trimming dies are usually, but not always, made from the same type of tool steel. Very abrasive or tough forgings may require more highly alloyed steels for trimming dies than are necessary for punches.

The forging, normalizing and annealing temperatures are given in the table on page 657.

Data on the heat treating of tools for hot and cold trimming are given in Table II.

Care should be used to obtain good alignment in mounting both dies and punches. Dies that are not flat on the bottom should be ground to assure firm and even seating.

Trimming dies should not be used after they are noticeably worn or dull, because when dies are in this condition, much higher pressures are developed in the trimming operation, and chipping or breaking may result.

In the resharpening of cutting edges the usual precautions should be used to avoid grinding stresses or cracks.

Table I. Approximate Chemical Compositions of Steels for Trimming Tools[a]

Steel No.[b]	C	Mn	Si	Cr	V	W	Mo	Co
Tools for Hot Trimming								
IIID	0.55	0.25	0.25	1.25	0.25 opt	2.50	0.50 opt	...

(a) The compositions given are type compositions only. Actual analyses of the steels they represent will vary a reasonable amount from these averages. It should be remembered that the more the composition of any steel varies from these averages, the more the treatment may differ from that recommended.

"Opt" indicates that the element so marked is optional in the composition. Steels have been found satisfactory either with or without the element present.

(b) These numbers are the ones used in the table of principal types of tool steels, page 656 in this Handbook.

Table II. Hardening and Tempering Treatments for Trimming Tools

Steel No.	Preheating Temperature,(a) deg Fahr	Hardening Temperature,(a) deg Fahr	Time at Temp, min	Quenching Medium	Tempering Temperature, deg Fahr	Hardness,(b) Rockwell C
IIID	1200	1700 to 1800	15 to 30	Oil	900 to 1150	50 to 45
IVA2	1300	1700 to 1800	15 to 30	Air	800 to 1000	50 to 45
IVC	1450	1800 to 1875	15 to 30	Air	1025 to 1100	50 to 45
IVF2	1550	2050 to 2150	2 to 5	Oil or air	1150 to 1225	50 to 45
IVF4	1550	2150 to 2250	2 to 5	Oil or air	1200 to 1250	50 to 45
IA(c), IC(c)	1200	1450 to 1500	10 to 20	Water	450 to 750	60 to 52
IIB2(c)	1450	1750 to 1800	10 to 20	Air	450 to 1100	60 to 52
IID2(c)	1500	1800 to 1875	15 to 45	Air	450 to 1050	60 to 52

(a) Heat rapidly from the preheating temperature to the hardening temperature.

(b) For cold trimming, a hardness of Rockwell C 55 to 57 is recommended for average trimming work involving larger forgings made of carbon, low-alloy, or intermediate-alloy steels. A hardness of Rockwell C 52 to 54 is recommended for trimming high-alloy steel forgings, intricate in design and having deep sections, or for trimming forgings at high hardnesses.

(c) A hardness of Rockwell C 58 to 60 is recommended for small simple tools used in cold trimming carbon and low-alloy steels.

The Composition and Heat Treatment of Solid Shear Blades

By the Subcommittee on Tool Steel

THIS article covers the heat treatment of solid shear blades and the steels most commonly used for hot and cold shearing of ferrous and nonferrous metals.

Chemical Composition. The approximate chemical compositions of the steels generally used for solid shear blades are given in Table I. Table II shows a grouping of the steels according to the nature of the work to be done and the service life desired.

In selecting a steel for heavy and extra heavy cold shearing, proper consideration must be given to the fact that shallow-hardening steels tend to spall on the cutting edge and that highly alloyed steels, which harden through, are likely to break out deeply or break in two.

Forging, Normalizing and Annealing. Recommendations for the forging, normalizing and annealing of the steels listed in Table I are given in the table on page 657 and in the article on page 653 of this Handbook.

Hardening. Hardening treatments are given in Table III. Reference should be made also to the article on page 653 of this Handbook, where the general methods and precautions are discussed.

Table II. Steels for Solid Shear Blades

Shearing Application	Steel
Cold Shearing	
Extra heavy and heavy materials (bars, billets and plate)	IA, IC, IIC (0.55% C), VIF3
Medium materials (bars, shapes, plate and strip)	IA, IC, IIC (0.55% C), VIF1, VIF3, IID1, IIB2
Light materials (strip, sheet and tin plate)	IA, IC, IIC (0.65% C), VIF1, IIB1, IIB2, IIC1, IID1, IID2, IID3, VC1
Hot Shearing	
Extra heavy materials (billets, blooms and slabs)	VIF2, IIID (0.40% C), IVB
Heavy materials (bars, billets and sheet bar)	IIC, IIID, IIIE, IVB, IVF1
Medium and light materials (bars, strip and sheet)	IID1, IVB, IVF3

Notes. The designation "light material" refers to stock no larger than ¼ in. in diam or thickness; "medium material", more than ¼ in. but no larger than ¾ in. in diam or thickness; "heavy material", ¾ to 4 in.; and "extra heavy material", more than 4 in.

For cold shearing, the carbon content of steels IA and IC is about 0.75% for heavy, 0.85% for medium and 1.0% for light work. For hot shearing, the carbon content is usually about 0.65% for heavy work and 0.75% for medium work.

(a) The compositions given are type compositions only. Actual analyses of the steels they represent will vary a reasonable amount from these averages. It should be remembered that the more the composition of any steel varies from these averages, the more the treatment may differ from that recommended.

"Opt" indicates that the element so marked is optional in the composition. Steels have been found satisfactory either with or without the element present.

(b) These numbers are the ones used in the table of principal types of tool steels, on page 656 in this Handbook. When note (d) follows the designation, the composition is a slight modification of that shown in the table of principal types.

(c) For limited service involving high shock but low abrasion.

(d) A slight modification of the composition given for this steel in the table of principal types of tool steels, page 656.

(e) For service involving intermediate amounts of shock and abrasion.

(f) For long-run service involving low shock and high abrasion.

(g) May contain optional amounts of cobalt or nickel or both.

(h) For long-run service involving shock and abrasion at elevated temperatures.

(i) For long-run service involving low shock but high abrasion at elevated temperatures.

(j) For long-run service, involving intermediate amounts of shock and abrasion and where the stock being sheared has a temperature as high as 1200 F.

(k) For flying pinch strip shearing. Used for hot shearing but not recommended for use at temperatures above 1500 F.

(l) In the absence of tungsten, it may be advisable to increase the molybdenum content to 2.00% when shearing temperatures are higher than 1900 F.

When it is practical, long thin blades should be heated and quenched in a vertical position to minimize sagging during heating and warping during quenching. Long heavy blades should be heated on a smooth, horizontal furnace floor to minimize sagging, and should be turned over frequently to permit uniform and thorough heating.

When quenching long heavy blades, it is recommended that the quenching bath be agitated, that the blades be quenched with the edge down, rather than with a flat side down, and that the blades be turned over, during the quench, to minimize warping.

Tempering. The temperatures given in Table III cover a wide range to indicate the hardening capacity of any steel. The type of material to be sheared determines the hardness requirement of the blade. For shearing thin material, the hardness should be on the higher side, and for heavy material and hot shearing, on the lower side.

Notes About the Process. Shear blades should be straightened during cooling from the hardening temperatures. A quick-acting straightening press, such as a hydraulic press with knife-edge supports, should be available to apply a quick, uniform pressure at the desired locations along the knife. For straightening during cooling from the hardening temperature, the shear blades should be withdrawn from the quenching bath at a temperature from 400 to 500 F, which is just below the point where the oil ceases to flash; or with water-quenched blades, just where the water steams or dries off the blades immediately. A shear blade should be straightened, if necessary, as soon as possible after tempering, while still hot.

Table III

Hardening and Tempering Treatments for Solid Shear Blades

Steel No.		Preheat Temperature, deg Fahr	Rate of Heating for Hardening[a]	Hardening Temperature,[b] deg Fahr	Time at Temperature, minutes	Quenching Medium	Tempering Temperature, deg Fahr	Range of Hardness, Rockwell C	Usual Working Hardness, Rockwell C[c]

(a) Steels preheated to 1450 F and higher may be transferred directly into the higher hardening temperature.

(b) The lower temperature of the range is intended for small cross sections, and the higher temperature for larger cross sections.

(c) The hardness requirements will vary with the cross section of the blade, gage or thickness and with the temperature of the metals sheared. Generally, the thinner the materials sheared, the higher should be the hardness of the blade. Also, the higher the temperature of the metals sheared, the lower should be the hardness. Ordinarily shear blades for shearing nonferrous metals should be 2 to 4 numbers (Rockwell C) lower in hardness than for corresponding gages of ferrous metals.

(d) Steel IIIC, when not containing molybdenum, may be water-quenched; when containing molybdenum, this steel should be oil-quenched.

(e) Steel IIIC (0.55% C), when intended for hot shearing, should be oil-quenched and tempered to Rockwell C 46 to 52, depending on the service temperature.

The Composition and Heat Treatment of Press Tools for Cold Shearing, Blanking, Punching, Forming and Coining

By the Subcommittee on Tool Steel

THE approximate chemical compositions of the steels generally used for dies and punches for cold shearing, blanking, punching, forming and coining, are given in Table I. Other steels less common than these may sometimes be used. Solid shear blades, forging press tools and trimming tools are discussed in other articles.

uniformly to the temperature specified and then bringing up to the hardening temperature more rapidly. However, very slow and uniform heating from room to hardening temperature is more helpful in preventing distortion.

Where pack hardening is suggested, refer for instructions to the general article on Forging and Heat Treating of Tool Steels, on page 653 in this Handbook.

Table I

Approximate Chemical Compositions of Press Tools for Shearing, Blanking, Punching, Forming and Coining[a]

VA3[c]	0.85	0.30	0.25	4.00	2.00	6.25	5.00
VC1[c]	0.70	0.30	0.25	4.00	1.00	18.00	...

(a) The compositions given are type compositions only. Actual analyses of the steels they represent will vary a reasonable amount from these averages. It should be remembered that the more the composition of any steel varies from these averages, the more the treatment may differ from that recommended.

"Opt" indicates that the element so marked is optional in the composition. Steels have been found satisfactory either with or without the element present.

(b) These numbers are the ones used in the table of principal types of tool steels on page 656.

(c) The carbon content may be lower for special purposes.

(d) 0.50% Ni optional.

(e) 3.50% Co optional.

(f) These steels are used both for dies and for punches, with the exception of steels IIIB, IIIC and IIID, which are used for punches only.

Forging, Normalizing and Annealing. The temperatures for these operations are given in the table on page 657. Instructions as to procedures may be noted in the article on page 653 or in articles dealing with the various types of steels under consideration.

Hardening and Tempering. The heat treatments are given in Table II.

Notes About the Process. Ordinarily both the punch and the die are made from the same steel. When the design of a die is intricate or when distortion is a factor, an air- or oil-hardening steel should be used, but for more simple designs a water-hardening steel may be used.

Steels IIA1, IIA2, IIA3, IIB1 and IIB2 can be preheated without the use of two furnaces, by heating slowly and

Steels IIC1 and IID2 absorb heat at a slower rate than the other steels. They should therefore be heated much more slowly. Steels IIB2, IIC1 and IID2 are sometimes pack hardened, especially if the die cannot be ground.

Most cold coining dies must have a deep hardness to prevent sinking under the high pressures developed, and also to permit redressing by grinding of flat dies. Press-coining dies usually are either flat or have relatively shallow impressions, and steels like IIA1, IIA2, IIA3, IIB1, IIB2, and IID2 are the most widely used.

For long-run tools and tools working on hard, abrasive materials, the more highly alloyed steels (the high-carbon high-chromium type and the high speed type) are used.

Table II

Hardening and Tempering Treatments for Press Tools

Steel No.	Preheat Temperature, deg Fahr	Rate of Heating for Hardening	Hardening Temperature, deg Fahr	Time at Temperature, minutes	Quenching Medium	Tempering Temperature, deg Fahr

The Composition and Heat Treatment of Cold Heading Dies

By the Subcommittee on Tool Steel

THIS article covers the processes to be followed in the heat treatment of cold heading dies made from the steels shown in Table I. The cold heading operation is discussed in the article on page 43.

Table I

Approximate Chemical Composition of Steels for Cold Heading Dies[a]

Steel No.[b]	C	Mn	Si	Cr	V	W	Mo	Co
IA, IB, IC	0.90	0.25	0.25	0.25 opt	0.20 to 0.50 opt	...	...	...
IA, IB, IC	1.10	0.25	0.25	0.25 opt	0.20 to 0.50 opt	...	...	...
IIB2[c]	1.00	0.50	0.25	5.00	0.50 opt	...	1.00	...
IID2[c]	1.50	0.35	0.35	12.00	0.50 opt	...	0.80	3.50 opt
VA2[c]	0.80	0.30	0.25	4.00	1.00	1.50	8.50	...
VC1[c]	0.70	0.30	0.25	4.00	1.00	18.00	...	...

(a) The compositions given are type compositions only. Actual analyses of the steels they represent will vary a reasonable amount from these averages. It should be remembered that the more the composition of any steel varies from these averages, the more the treatment may differ from that recommended.
"Opt" indicates that the element so marked is optional in the composition. Steels have been found satisfactory either with or without the element present.
(b) These numbers are the ones used in the table of principal types of tool steels on page 656.
(c) Used primarily for inserts.

Stress Relieving. Dies and headers that are cold hubbed should be heated to between 1250 and 1350 F and slowly cooled before hardening. If much metal is moved in hubbing, alternate stress relieving and hubbing operations are necessary.

Forging, Normalizing and Annealing. See table on page 657, and the article on page 653 of this Handbook.

Hardening. Preheating is often advantageous in order to insure thorough heating and to shorten the time required in the hardening furnace. Preheating and hardening temperatures are shown in Table II. Dies should be heated slowly and uniformly.

Solid dies of relatively small cross section are usually quenched through the hole only. Large dies may be immersed in the quenching solution while the coolant is forced under pressure through the hole.

When hardening open dies, care must be taken to avoid gas pockets in the die impressions. This is done best by a jig that forces the quenching medium against the surface to be hardened.

When hardening heading dies, it is essential that a uniform and sufficient depth of hardness be obtained to resist the pressures developed in the heading operation.

Some small, solid cold heading dies are made from steels IIB2 and IID2, but these steels are generally used for inserts.

Table II

Hardening and Tempering Treatments for Cold Heading Dies

Steel No.	Preheat Temperature, deg Fahr	Hardening Temperature, deg Fahr	Quenching Medium	Tempering Temperature, deg Fahr
IA, IB, IC (0.90% C)	1000	1500 to 1650[a]	Brine or water[b]	300 to 600
IA, IB, IC (1.10% C)	1000	1450 to 1600[a]	Brine or water[b]	300 to 600
IIB2	1450	1700 to 1750	Air	400 to 600
IID2	1450	1800 to 1850	Air	400 to 600
VA2	1500	2150 to 2200	Oil, air or molten bath[c]	1000 to 1150
VC1	1500	2200 to 2300	Oil, air or molten bath[c]	1000 to 1150

(a) The size and shape of the die, the character of the impression and the character of the stock to be headed will determine whether the high or low temperature is better.
(b) For quenching open dies without a jig, brine is preferable to water.
(c) Air or molten bath quench is preferable to minimize distortion.

Tempering. Tempering should be started immediately after quenching. Time at temperature should not be less than one hour and longer periods are advisable.

The tempering temperature is governed by the type of die and the material to be headed. For extrusion dies and inserts, a minimum hardness of Rockwell C 59 is usually necessary.

Notes About the Process. If decarburized surfaces cause difficulty, a light coating of boric acid during the heating period may help to overcome the trouble. This coating is applied by quickly dipping the preheated die into a hot, saturated solution or by sprinkling the powder on the preheated die.

When hardening solid dies and headers with deep impressions, it is essential to quench in a jig that forces the coolant, under pressure, into the impression or through the hole in such a way that the forming of all gas pockets is avoided and plenty of fresh coolant impinges against the surfaces to be hardened.

High speed steels have been given considerable recognition as a material suitable for cold heading die inserts, particularly for that class of cold heading work requiring close tolerances and a die steel that will withstand high abrasive action.

Parts of rather intricate design can be cold formed with favorable production performance from dies made with high speed or chromium air-hardening die steel inserts. The inserts are suitably shrunk or fastened into a holder made from a medium-carbon low-alloy steel to provide the necessary support. It is very important that such an insert be fitted carefully into a holder; otherwise cracking in service will result.

The Composition and Heat Treatment of Thread-Rolling Dies

BY THE SUBCOMMITTEE ON TOOL STEEL

THIS article covers the heat treatment of thread-rolling dies made from steels of the approximate compositions shown in Table I. Other grades of steel are sometimes used for such dies, but in relatively small amounts. The thread-rolling operation is discussed on page 44.

Machining. In preparing the steel for the milling operation, it is essential that sufficient stock should be machined off to insure the removal of all surface defects and traces of decarburization. The steel must be uniformly annealed to prevent injury to the expensive thread-milling hobs. Speed of milling should be adjusted to obtain the smoothest possible finish on the threads, since this is helpful in increasing die life. After the thread form has been milled on the die face, all traces of oil and chips should be removed from the die before hardening. After the dies have become worn in use, they are often annealed and planed off. Thereafter new threads are milled and the dies are hardened and tempered for further use. For annealing, the dies should be carefully packed in sealed containers, along with suitable packing material. For annealing temperatures, see the table on page 657 and the article on page 653. Some thread-rolling dies are ground from solid hardened blanks.

Stress Relieving. After machining, a stress-relieving treatment at 1100 to 1200 F is often beneficial in preventing distortion of the teeth during subsequent heat treatment.

Hardening. In order to minimize distortion it is essential to heat all thread-rolling dies slowly throughout the heating cycle and to hold until heated through. This is particularly important with the more highly alloyed steels. The die should be tempered as soon as it is cool enough to hold in the bare hands.

Dies made from steels IIB2 and IID2 are usually pack hardened or heated in controlled-atmosphere furnaces to prevent decarburization. Burnt cast-iron chips, or pitch coke that has been heated to approximately 2000 F to remove all volatile matter, may be used for the packing medium. The box should be heated slowly to between 1250 and 1300 F, held until a uniform temperature is reached throughout the box, then heated gradually to the hardening temperature (*see* Table II), and held until a uniform temperature obtains in the charge. When hardening in controlled-atmosphere furnaces, the dies should be soaked for 15 to 30 min. Then the dies should be removed from the pack and air-cooled to room temperature, after the adhering particles are brushed off.

Table II. Hardening and Tempering Treatments for Thread-Rolling Dies

Steel No.	Preheating Temperature, deg Fahr	Hardening Temperature, deg Fahr	Quenching Medium	Tempering Temperature, deg Fahr
IIB1	1250	1450 to 1600	Air	300 to 500
IIB2	1450	1750 to 1800	Air	400 to 600
IID2	1500	1800 to 1875	Air	400 to 950
VA3	1500	2150 to 2225	Oil or molten bath	1050 to 1150
VC1	1600	2250 to 2300	Oil or molten bath	1050 to 1150

Tempering. In tempering, dies should be heated slowly to the temperature shown in Table II, preferably in a circulating-air type of furnace, and held at temperature for a minimum of 2 hr. Longer tempering times are desirable. In general, a hardness of Rockwell C 58 to 59 is satisfactory on softer materials and about 60 to 61 on harder stock.

Table I

Approximate Chemical Compositions of Steels for Thread-Rolling Dies[a]

Steel No.[b]	C	Mn	Si	Cr	V	W	Mo	Co
IIB1	0.90	2.50	0.30	1.50	...	...	1.00	...
IIB2	1.00	0.50	0.25	5.00	0.50 opt	...	1.00	...
IID2	1.50	0.35	0.35	12.00	0.50 opt	...	0.80	3.50 opt
VA3	0.85	0.30	0.25	4.00	2.00	6.25	5.00	...
VC1	0.70	0.30	0.25	4.00	1.00	18.00	...	...

(a) The compositions given are type compositions only. Actual analyses of the steels they represent will vary a reasonable amount from these averages. It should be remembered that the more the composition of any steel varies from these averages, the more the treatment may differ from that recommended.

"Opt" indicates that the element so marked is optional in the composition. Steels have been found satisfactory either with or without the element present.

(b) These numbers are the ones used in the table of principal types of tool steels on page 656.

The Composition and Heat Treatment of Die-Casting Dies and Permanent Molds

BY THE SUBCOMMITTEE ON TOOL STEEL

METALLIC molds are used exclusively in die casting and permanent mold casting. Some applications of centrifugal casting also use metallic molds.

Detailed information on the methods of casting may be found in the NONFERROUS METALS SECTION of this Handbook.

Table I lists the steels in common use for die-casting dies and permanent molds. Certain preferences are indicated but other steels may be used.

The composition and heat treatment will depend principally on the operating temperature. In dies for casting zinc- and lead-base alloys — relatively low-temperature work—carbon steels may be used without heat treatment. Aluminum- and magnesium-base alloys require heat treated alloy steels. Copper alloys require special steels and heat treatments. For die casting zinc-base alloys, high-grade carbon steel may be used; but certain alloy steels of the chromium-vanadium and chromium-molybdenum types are particularly popular, and these are heat treated for long runs. Nitralloy and nitrided alloy steels are desirable in uses where resistance to wear and erosion is important.

Chemical Composition. The chemical compositions given in Table I are representative of the steels commonly used for die-casting dies and permanent molds. The usual applications for these steels are indicated in Table II.

Forging, Normalizing and Annealing. See the table on page 657 and the article on page 653 of this Handbook.

Hardening. Table III presents the accepted hardening heat treatments for these steels. Dies should be heated for hardening in furnaces with atmosphere suitably controlled or in salt baths—particularly dies for die casting, where the maintenance of dimensions and freedom from scaling and pitting of the working surface are desired. When the other methods are not available, pack hardening is used on steels requiring temperatures higher than

Table I

Approximate Chemical Compositions of Steels for Die-Casting Dies and Permanent Molds[a]

Stainless 410	0.10	0.80	0.80	12.00	...	...	...	...	...

(a) The compositions given are type compositions only. Actual analyses of the steels they represent will vary a reasonable amount from these averages. It should be remembered that the more the composition of any steel varies from these averages, the more the treatment may differ from that recommended.
"Opt" indicates that the element so marked is optional in the composition. Steels have been found satisfactory either with or without the element present.
(b) The first five steels are designated according to the numbers used in the table of principal types of tool steels, page 656.
(c) A modification of the composition given for steel VIG on page 656.

1650 F. Many die failures are caused by carburized or decarburized surfaces, resulting from the use of improper packing compounds or atmospheres. Carburization is probably the most dangerous and common result of pack hardening, because carbonaceous materials are ordinarily used.

Packing for Pack Hardening. New cast-iron chips are carburizing at temperatures above 1650 F, but this effect diminishes with use. Mixtures of new and spent chips have been used successfully as high as 1800 F. The chips must be clean.

Table II

Applications of Steels for Die-Casting Dies and Permanent Molds

Steel No.	Application
IIIA	Long-run dies for die-casting zinc-base alloys; permanent molds for gravity casting aluminum or magnesium. Used in the heat treated condition.
IVB	Dies for die-casting copper-, aluminum-, and magnesium-base alloys; permanent molds for gravity-casting alloys that have higher melting points. Used in the heat treated condition.
IVF1	Permanent molds for gravity casting. Dies for die-casting brass. Used in the heat treated condition.
VIF1	Permanent molds for gravity casting low-melting alloys. Used in the normalized and tempered condition at a hardness of about 300 Brinell.
VIG mod	Dies for die casting zinc-, tin-, and lead-base alloys. Used in the normalized or quenched and tempered condition, depending on casting conditions. For zinc-base alloys, usually quenched and tempered.
Nitralloy G	Used in nitrided condition for moving parts of dies, such as cores or slides.
Stainless 410	Permanent molds.

Note. Meehanite and gray cast iron are also used for permanent molds and SAE 1020 to 1045 for die-casting dies for low-melting alloys.

Aluminum oxide of mesh size 8 to 12 has been found safe for temperatures between 1750 and 2050, if the aluminum oxide is burned out prior to use. An addition of a small amount of spent charcoal has been found beneficial. At the higher temperatures indicated, a slight, easily removable scale may be formed.

Pitch coke of mesh size 6 to 8 is highly satisfactory in the range from 1700 to 2100 F when properly prepared. This preparation consists of holding the pitch coke at 2000 F in a closed chamber until the volatile matter is removed. Double heating is recommended when high-temperature packing is desired. Below 1700 F spent pitch coke is decarburizing in action.

Regardless of what material is used for packing, the packing box should be well sealed to prevent the admission of furnace gases.

Rates of Heating. Warping and change of size and shape may be reduced to a minimum by slow rates of heating. For this reason large dies should not be heated at a rate exceeding that which will give a total heating time of 1½ hr per in., measuring the greatest thickness of the die plus packing material. Frequently it is necessary to heat more slowly to minimize distortion.

Tempering. Table III gives temperature ranges for the tempering of these steels. After quenching, the steels should be tempered as soon as they are cool enough to be held in the bare hands. Tempering furnaces should be reduced in temperature to between 200 and 400 F before the dies are placed inside; this precaution will avoid excessive heating rates and uneven heating. Dies should not be quenched from the tempering temperature.

Tempering temperatures are selected to produce the hardness that gives the best results, according to experience. Dies are frequently tempered on the low side of the temperature range. The hardness is then determined and a second tempering treatment is given, at a slightly higher temperature if necessary, to produce the desired hardness. This process eliminates the chance of overtempering and provides the benefit of a double temper in higher alloy steels.

Notes About the Process. For aluminum-base or copper-base die castings, the alloy steel dies are water-cooled in service and should be preheated (usually to about 350 F) with water flowing slowly through the die. This practice prevents the serious damage likely to result from introducing cold water into a hot die.

Table III. Hardening and Tempering Treatments for Die-Casting Dies and Permanent Molds

Steel No.	Hardening Temperature, deg Fahr	Time at Temperature, minutes	Quenching Medium	Tempering Temperature,[a] deg Fahr	Hardness, Rockwell C
IIIA	1600 to 1700	30 to 60	Oil	800 to 1000	45 to 40
IVB	1800 to 1850	30 to 60	Air	1100 to 1200	45 to 35
IVF1	2000 to 2150[b]	Do not soak	Air or molten bath	1150 to 1250	45 to 37
VIF1	1500 to 1550	30 to 60	Oil	1200 to 1300	35 to 30
VIG mod	1550 to 1600	30 to 60	Oil	500 to 900	35 to 25
Nitralloy G	See the article on nitriding, page 697 of this Handbook				
Stainless 410	1800 to 1850	15 to 30	Air	800 to 950	40 to 35

(a) Time at the tempering temperature is usually about 2 hr per in. of greatest thickness. It is not uncommon to allow a total time of 10 to 12 hr for heating die blocks.
(b) Preheat at 1500 F.

The Composition and Heat Treatment of Plastic Molds

By the Subcommittee on Tool Steel

THIS article deals with the composition and heat treatment of the steels generally used for plastic molds and hubbing. Plastic materials, derived from phenol, urea, rubber, casein and other bases, are molded to shape in steel molds. Usually this forming is done at an elevated temperature. The dimensions and surface condition of the finished article are governed by the corresponding surfaces of the mold. Cleanliness, ease of fabrication, resistance to abrasion and to deformation, and uniform heat treating properties are necessary in the mold materials.

The die impression is formed by hubbing, by a machining operation or by a combination of the two. Hubbing consists of sinking the die impression cold with a master hub. This is often done in several operations with intermediate annealing. Low-carbon steels fully annealed are used for hubbed molds, subsequently carburized. Where the conditions are such that hubbing steels cannot be used, the dies are cut by machine.

Cleanliness. In order to insure freedom from internal defects that might mar the surface of the finished mold, the deep-etch test and magnetic particle inspection are used. Under operating pressures and temperatures, internal defects tend to open up and leave ridges or imperfections on the surface of the mold.

Fabrication. Some molds are shaped largely by hubbing, some by machining, and others by a combination of both processes. The depth to which a hub can be driven, as well as the power needed for the operation, depends largely on the hardness of the mold steel when annealed. This in turn depends on composition; a carbon steel can be annealed considerably softer than an alloy steel of the same carbon content. Consequently the steels that hub easily do not usually make so strong a mold as steels more difficult to hub. The selection of the steel will therefore be a compromise among final strength, wear resistance and hubbing properties.

Free-machining properties and good finish are desirable in mold steels that must be machined to shape. Since cleanliness is an important factor, the high-sulfur types are not desirable; therefore it is necessary to depend on careful annealing for the required machining properties.

Resistance to Abrasion and Deformation. Wear resistance is of great importance on long-run dies. Resistance to abrasion is increased by the addition of carbon and alloying elements. Strength is vital in dies that have thin sections, or in large dies where an entire surface may sink under heat and pressure. In large dies of this sort, when a case-hardening steel is used, core hardness is of considerable importance.

Uniform Heat Treating Properties. In the cost of producing dies for plastics, an important factor is stoning, machining or grinding to size after heat treatment. These operations are minimized by several precautions, such as protection from scaling by heat treatment in a controlled atmosphere, use of borax or copper plating, pack hardening and salt bath hardening. The use of air- or oil-hardening steels to minimize distortion, and the use of stress relieving to minimize machining stresses after rough machining are other methods of reducing final cost. Care must be taken in water- or oil-quenching to flush the impression thoroughly, in order to avoid soft spots. In steels subject to temper brittleness, the tempering range from 400 to 800 F should be avoided.

Composition and Heat Treatment. The approximate compositions of mold and hub steels are given in Table I. Forging, normalizing and annealing data are listed in the table on page 657. If annealing is required between hubbing operations, subcritical temperatures should be used. Hardening and tempering treatments are indicated in Table II.

Notes About the Process. Steel VIA is used for molds when ease of hubbing the impression is of primary importance. This steel is carburized and heat treated to give a surface hardness of Rockwell C 58 to 64. It is generally applied to molds for short-life applications, and to molds that have small or medium-sized cavities, involving low molding temperatures and pressures. Steel VIA is low in cost, distorts a moderate amount in hardening and has fair strength and wear resistance as well as considerable toughness. It machines with difficulty in the annealed condition but machines somewhat better after cold working by hubbing.

Steel VIB is a good general-purpose mold steel, applicable to the manufacture of almost all types of molds. It can be hubbed easily, although less easily than steel VIA. Steel VIB is case hardened and used at about the same hardness as steel VIA. It can be used for medium-life applications, for molds that have small or medium-sized cavities, involving moderate molding pressures and temperatures. It is quite low in cost, distorts moderately in hardening, has slightly more strength and wear resistance and greater toughness than steel VIA. Steel VIB can be hardened in either brine or oil without danger of soft spots.

Steel VIC is used for severe service conditions. Molds made from this steel can be hubbed or machined and are used after case hardening to about Rockwell C 55 to 62. The case and core strength and toughness exceed that ob-

(a) The compositions given are type compositions only. Actual analyses of the steels they represent will vary a reasonable amount from these averages. It should be remembered that the more the composition of any steel varies from these averages, the more the treatment may differ from that recommended.

"Opt" indicates that the element so marked is optional in the composition. Steels have been found satisfactory either with or without the element present.

(b) These numbers are the ones used in the table of principal types of tool steels, page 656.

(c) A modification of steel VIG.

(a) A modification of Steel VIG.

tainable with steel VIA. The life of molds made from this steel is long; the pressures may be high; distortion during heat treatment is low.

Steels IIA1 and IIA2 are used for making machined molds. These steels are more expensive, initially, but because of their "nondeforming" properties, savings are often made in finishing operations after heat treating. These steels harden to about Rockwell C 60 to 63, have very high abrasion resistance, resist high pressures and have moderate toughness.

Steel VID is commonly used where corrosion resistance is desired. This steel is used at lower hardnesses than the steels previously mentioned. It has extremely high strength and good toughness and gives moderate resistance both to abrasion and to the softening effect of high temperatures.

Steel IID2 is used where high abrasion and heat resistance are desired. It has excellent "nondeforming" properties and moderate shock resistance. The cost of this steel is high and machining and grinding properties are poor. High speed steel has similar properties and has been used for similar applications. The use of steel IID2 is justified only for long-run applications.

Dies cast to shape are sometimes used with saving of time and labor. Such dies usually have a composition similar to that of steel IID2.

In certain applications where large impressions are involved, heat treated die blocks can be purchased at hardnesses as high as 400 Brinell, and the impression can be machined without subsequent heat treating. Steel VIG is typical of material processed in this manner. Material of this type is also available in specially treated free-machining die blocks, heat treated to a hardness of Rockwell C 45 to 52 with only moderately increased machining resistance.

Carburizing Methods

BY R. B. SCHENCK*

IN modern practice, the process of carburizing is applied to ferrous metal with the object of increasing the carbon content of the surface and in some cases the nitrogen content as well, so that when subjected to suitable heat treatment, the surface portion thus carburized will be substantially harder than the underlying metal. The combined processes of carburizing and hardening have long been known as "case hardening".

This combination of hard surface and softer interior, made possible by case hardening, is of inestimable value in modern engineering practice. By the use of alloy steels, great strength and toughness in the core can be combined with extreme surface hardness, resulting in a composite structure capable of withstanding certain kinds of stress to a high degree. For less exacting requirements, there are many applications where low or moderate core properties, together with a high degree of surface hardness, can be obtained with cheaply fabricated, low-priced carbon steels.

Commercial carburizing may be accomplished by any one of the following methods: (1) pack carburizing, (2) gas carburizing, (3) carbonitriding, or (4) liquid carburizing.

For pack carburizing, the work material is heated in contact with a solid carburizing compound in a closed container. In the gas method, the metal is exposed to a carburizing gas in a heated chamber. For carbonitriding, the metal is heated in the presence of a gaseous mixture containing both carburizing gas and ammonia. In liquid carburizing, the work material is immersed in a fused carburizing salt. Methods (1) and (2) add only carbon in producing the case; methods (3) and (4) add both carbon and nitrogen.

A choice of the method to be used depends on so many factors that it becomes very difficult to set up any definite rules to be followed. The design of the part, composition of the steel, type and depth of case, permissible distortion, production volume, initial investment, and operating cost must all be considered; and together these factors present such an involved picture that the only correct procedure is to judge each situation on its own merits.

Pack Carburizing. The pack method is the oldest and for years has been the one most extensively employed. Modified in various ways, pack carburizing has been used for virtually every kind of article that could be carburized, ranging from typewriter parts to armor plate. Ordinarily this is considered the most foolproof of the four methods, and the safest to use in the absence of trained supervision.

The usual form of the pack method, commonly referred to as "box carburizing", lends itself readily to either batch or continuous furnace operation. The principal disadvantages are the time consumed in heating the charge, the high cost of labor for packing and unpacking, and the preclusion of automatic quenching.

The only other form of pack carburizing that deserves mention here is the "rotary retort" method, suitable only for batch operation. For parts that can withstand rough handling, it is probably the most economical method yet devised.

Gas Carburizing. Gas carburizing, for both batch and continuous operation, has recently undergone intensive development and, according to present indications, may eventually replace other methods to a great extent.

Noteworthy improvements have been made in equipment for continuous gas carburizing with either automatic quenching, hand quenching, or slow cooling. Batch furnaces for gas carburizing have likewise been greatly improved. Better sealing, more positive controls and forced circulation of the gas around the work material, have contributed greatly to the dependability of the process.

An important characteristic of gas carburizing is that the carbon content of the case can be controlled effectively by suitable adjustment of the gas composition.

One of the oldest commercial forms of gas carburizing is the rotary retort method, very similar to the one described under Pack Carburizing, but using gas instead of solid carburizing compound. In general, the same advantages and limitations apply to both.

Carbonitriding. From a commercial standpoint this process is relatively new. It is used principally for light cases (usually not more than 0.020 in. deep) produced at moderate temperatures. Like gas carburizing, it is readily adapted to either batch or continuous operation. Continuous furnaces are in use at temperatures between 1500 and 1550 F, producing large quantities of carbonitrided parts with case depths from 0.003 to 0.010 in. Many of these parts were formerly hardened by cyaniding. If the gas contains a sufficient percentage of ammonia, carbon steel parts can be made file-hard without quenching.

Liquid Carburizing. Progress in the technique of liquid carburizing, with respect to both the carburizing agent and the equipment, has been extremely rapid in the last few years. The new activated baths with their higher rate of penetration and better quality of case, together with im-

McQuaid (Consultant, Cleveland), R. G. Peters (Warner Gear Division, Borg-Warner Corporation) and G. T. Williams (Pratt & Whitney Aircraft Division of United Aircraft Corporation).

proved methods of heating and control, are extensively replacing the old cyanide pot in the more progressive plants. Continuous operation and automatic handling have been used successfully in a number of installations. Liquid carburizing is used mostly for light cases at moderate temperatures. For case depths of more than 0.030 in. other methods are usually employed. The process is extremely flexible, easily controlled and particularly well adapted to small units. An important use of liquid carburizing is for local hardening by immersing only the portion to be hardened. The largest single item of operating expense is ordinarily the carburizing salt.

The Mechanism of Carburization

By F. E. Harris*

THE CARBURIZATION of steel may be considered on the basis of two fundamental concepts. The first is diffusion, influenced by the properties of the steel, and concerned with the movement of carbon in the steel itself; the second deals with the source supplying the carbon, and with the transfer of carbon to the steel surface.

These two general concepts may be described briefly:

1 Fick's law of diffusion is

$$\frac{dm}{dt} = -SD\frac{dc}{dx},$$

where dm/dt may be taken as the time rate of flow of the solute, carbon, through the area S. This rate is proportional to the area itself, where D is the proportionality factor or diffusion coefficient. The rate is also proportional to another factor, dc/dx, which expresses the rate at which the carbon concentration c varies with the depth x. The flow of carbon in gamma iron is in part analogous to the flow of heat in solids, and to some extent expressions developed for the conduction of heat are applicable.[1, 2]

2 The equilibrium state for chemical reactions may be represented by numerical constants, K_p, derived from the general expression

$$\log K_p = \frac{A}{T} - B$$

where K_p is a numerical factor termed the "equilibrium constant", which is derived from the values for the concentrations of the reactants and products of a chemical reaction. The subscript p denotes the dependency of the chemical reaction on pressure. T is the absolute temperature at which the reaction takes place. A and B are constants derived for the particular reaction.

Instead of being developed in a formal way from the basic principles, the mechanism of carburization may be analyzed from the viewpoint of carbon flow, by stating the controlling factors. These factors may be divided for discussion into two distinct classifications: (1) factors that control the flow of carbon in steel and (2) factors that influence the transfer of carbon to the steel surface.

The mechanism will be explained in that order.

The Flow of Carbon in Steel. A solution has been defined as any phase of which the composition may vary continuously within certain limits. Carburizing is concerned with the solid solution of carbon in austenite. The limits of carbon content of this phase depend on the temperature and the composition of the steel.

The rate of flow of carbon in austenite depends on values for the diffusion coefficient and characteristics of the concentration gradient. The diffusion coefficient is in turn a function of temperature and carbon concentration. The diffusion of carbon proceeds from the higher concentration, developed from the supply source, to the lower concentration of the core; when the concentration limits (surface and core) are maintained consistently, the form of the gradient may be predicted for any given and constant temperature of operation. The form of the gradient, under certain known and standard operating conditions, is described by a simple function of the elapsed time.

* Buick Motor Division, General Motors Corporation, Flint, Mich.

Prepared for the Subcommittee on Carburizing

Concentration Limits. The iron-carbon phase diagram as commonly drawn represents, by the A_{cm} line, the variation of solubility of carbon in austenite with variation of temperature in plain carbon steels. The common alloying elements tend to move the cementite line to the left. Figure 1, derived from carburizing experiments, shows the approximate limits of surface concentrations for eight common carburizing steels.[3]

Carbon Gradients. The general form of the carbon gradient is influenced only by the range of concentration, from surface to core. For a given temperature, the rate

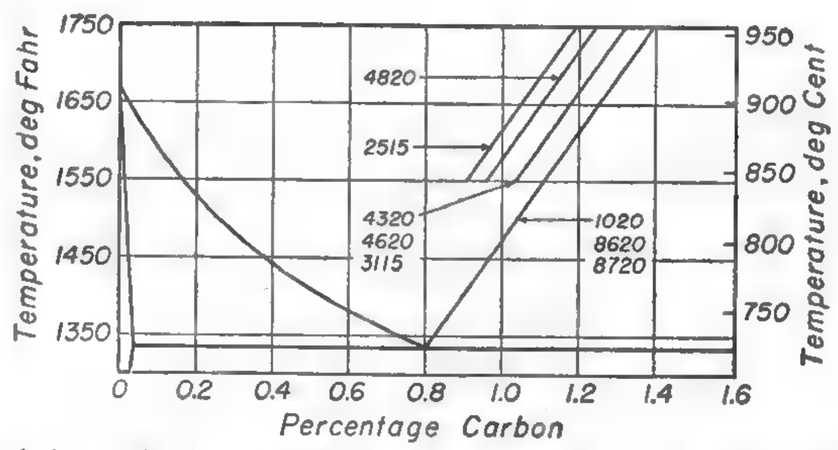

Fig. 1 Approximate solubility of carbon in austenite for eight steels

of diffusion increases with increasing carbon concentration. For the common carburizing steels and practice, the surface concentration limits are from 1.0 to 1.3% C with core concentrations usually from 0.12 to 0.25% C. For this range of concentrations, a single gradient form may be derived without great error. This is done by adopting a special standard for the co-ordinate scales on which any C-X (concentration-depth) curve is plotted. Thus the unit of concentration may be taken as the difference between the actual percentage of carbon at the surface and the per-

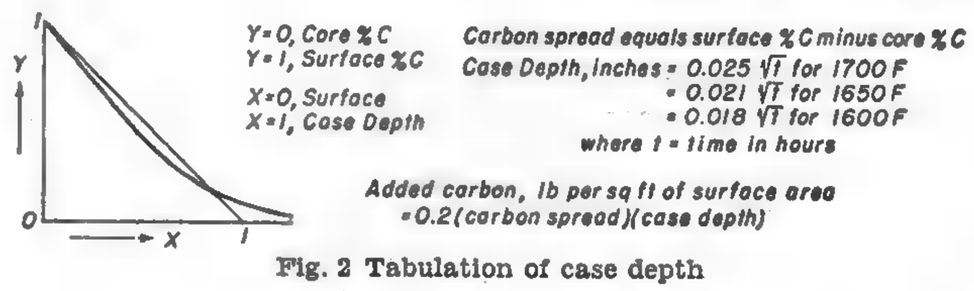

Fig. 2 Tabulation of case depth

centage of carbon in the core. This difference is called "carbon spread". A similar treatment for the depth or X ordinate brings out the significance of the term, "case depth", so that, for the standard gradient, the C-X curve becomes the plot for carbon spread versus case depth. The concept aids materially in evaluating and comparing carbon gradients.

For its attainment, the standard carbon gradient obviously requires a constant temperature of operation and a sufficient supply of carbon to the steel surface.

Case Depth. A straight line may be drawn, closely simulating a given gradient, so that the area enclosed between the line and the co-ordinates equals the area between the actual gradient and the axis.[3] Such a line intersects the concentration axis at a point representing the surface concentration. The point where this line intersects the depth axis designates the total case depth.

The slope of this line is a function of the scale chosen

for the carbon spread compared with the scale taken for case depth. The choice of equal units on the scale is taken arbitrarily as a standard, and the general form of the actual gradient may be represented (Fig. 2). Since the rate of diffusion increases with temperature, the case depth must be expressed for given and constant temperatures. For the conditions stipulated, the case depth will be directly proportional to the square root of the time factor.

Readings of case depth, when thus determined, closely approach the measurements obtained from the etch test, and for ordinary operations will represent a point about 0.07% C higher than the actual concentration of the core. From the representation of the gradient in Fig. 2, a relative depth can be estimated readily for any desired minimum of carbon concentration (or effective case). The particular value of this definition of total case depth is found in facilitating evaluations of gradients.

Added Carbon. From the construction of the case depth, the amount of carbon added through a unit surface area may be readily derived. Thus for an area of 1 sq ft or 144 sq in., the effective volume of steel expressed in cubic inches is 144 × (case depth in inches). The weight of this volume in pounds is 144 × 0.28 × (case depth) or 40 × (case depth). The average increase in percentage concentration is represented by one-half the carbon spread, and the numerical factor for carbon added during carburi-

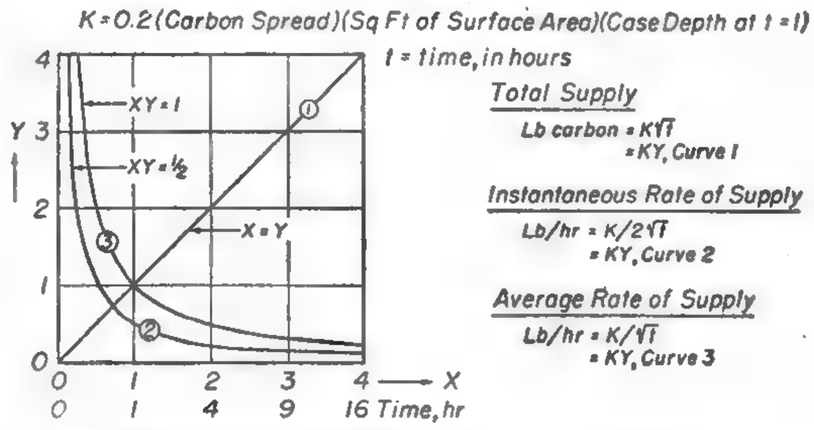

Fig. 3 Rates of carbon demand for standard gradient

zation becomes ½ × 1/100 × (carbon spread). Thus the amount of carbon in pounds added through each square foot of surface area is

$$\frac{40\ (\text{case depth})\ (\text{carbon spread})}{200}$$

or 0.2 (case depth) (carbon spread) where the case depth is expressed in inches and where the carbon concentrations from which the value for carbon spread is derived are expressed in weight percentages.

Rates of Carbon Demand. The carbon added through the surface area is directly proportional to the case depth, and thus is also a function of the square root of the elapsed time of carburization. The number of pounds of carbon added in the first hour for a given area may be designated by K. The total number of pounds of carbon added for a given time t then becomes $K\sqrt{t}$, where t is the time in hours. The instantaneous rate at which the surface demands carbon to maintain the surface concentration, at a given elapsed time t, is then $K/(2\sqrt{t})$; the rate is expressed in pounds per hour. The average rate for a given elapsed time is twice the instantaneous rate.

Figure 3 shows the graphs and presents the derivation for the rates of demand that must be matched by the source of the carbon supply in order to obtain the standard gradient. The rate curves may be readily interpreted for any given time or time interval on the X ordinate; the scale unit is the square root of the time in hours. The corresponding Y value from the graph, multiplied by the K factor, will give the rate of demand for carbon in pounds per hour.

Diffusion Coefficients. Although the concentration gradient may be standardized without great error for the surface and core concentrations commonly found in carburization, the actual concentrations that limit the gradient have a pronounced effect on the form of the gradient. This phenomenon is explained by the dependency of the diffusion coefficient, and thus the diffusion rate, on the concentration itself. This coefficient increases with increasing carbon concentration.[4] The influence of concentration on the form of the gradient may be shown by comparing the gradients for carburizing and decarburizing, obtained at equal temperatures and times, with the limiting concentrations approximately equal for both operations. The rate of diffusion as affected by concentration will have little variation when the concentrations bounding the gradient are close together. When the carbon spread is low, the gradient

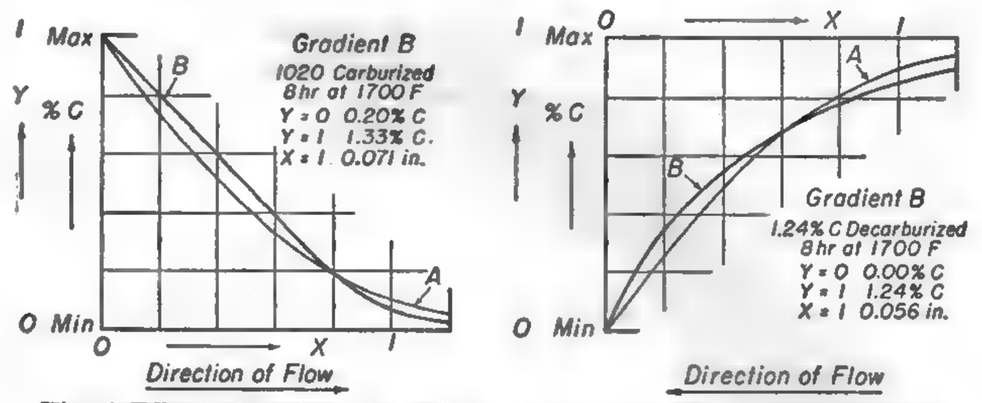

Fig. 4 Effect of carbon spread on gradients in the austenite phase

is represented by curves A in Fig. 4. These curves are shown to be identical in form. The actual gradients for fairly wide carbon spreads are shown in curves B. It will be noted that the divergence from curve A is opposite in direction for the two operations. The reason for this is apparent since, for decarburization, the rate of diffusion at the surface, where the larger portion of the total carbon is abstracted from the steel, is low because of the low value of concentration; for the carburizing operation, the concentration at the surface is high, and thus a high rate of diffusion is found where the larger portion of the total carbon is added to the steel.

The Ferrite Phase. The factors that limit the flow of carbon may also require a consideration of the ferrite phase and the interface between ferrite and austenite.[8,9] Except at very low carburizing temperatures, the minimum concentration of carbon in austenite is usually exceeded by the core concentration and, in general, carburization is concerned solely with the austenite phase. For temperatures between the A_3 and A_1 points, when the supply depletes the surface carbon (decarburization) to a concentration value below that of saturated ferrite (the maximum

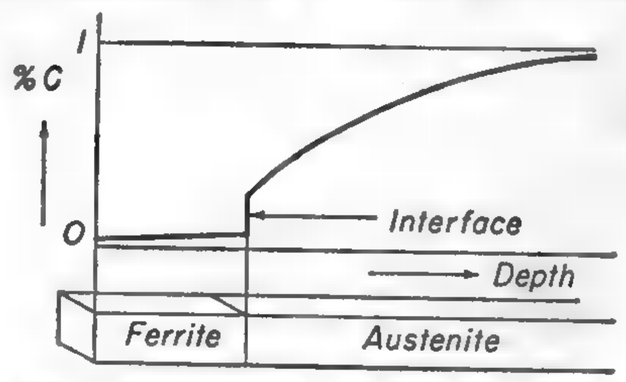

Fig. 5 Decarburizing 1.0% C steel at 1500 F (schematic)

solubility of carbon in ferrite is 0.025% C) the ferrite phase may be the controlling factor in carbon flow. At 1500 F it is possible to abstract more carbon from the surface of a 1.0% C steel by decarburization than can be added to a bar of equivalent surface area by the carburization of a 0.24% C steel for equal conditions of time and temperature. These data are consistent with the recent calculations of Polder,[5] which indicate that, at a given temperature, the coefficient of diffusion of carbon in ferrite is greater than that of carbon in austenite. A schematic gradient for the decarburization of a high-carbon steel is shown in Fig. 5, for ferrite and austenite. The ferrite-austenite interface is also illustrated (Fig. 6) by carburizing ■ sample of very low carbon content at a temperature slightly above A_1.

The Cementite Phase. The decarburization of cast iron can be used to demonstrate the equilibrium (lack of flow) between cementite and saturated austenite. The micrograph of Fig. 7 shows the interface between austenite and cementite in a decarburized white cast iron.

Flow of Carbon from the Supply Source. The primary function of carburizing mediums is to furnish an adequate

supply of carbon to the steel surface. The transfer of carbon from the source of supply to the steel is involved with reactions occurring at this surface. The carburizing agent responsible for the actual transfer of carbon is a carbon compound. The extent to which various carbon compounds may supply carbon is related to the conditions that determine the equilibrium with the surface carbon of the steel. The equilibrium composition of the reactants and products is a function of temperature and also of the carbon concentration at the surface.

The equilibrium composition is a condition involving no transfer or flow of carbon. The maximum availability of carbon in a given carbon compound is represented by the excess above the composition in equilibrium with the steel surface. The availability of a given agent decreases with increasing surface concentration and is lowest at the upper limit of carbon solubility (saturated austenite).

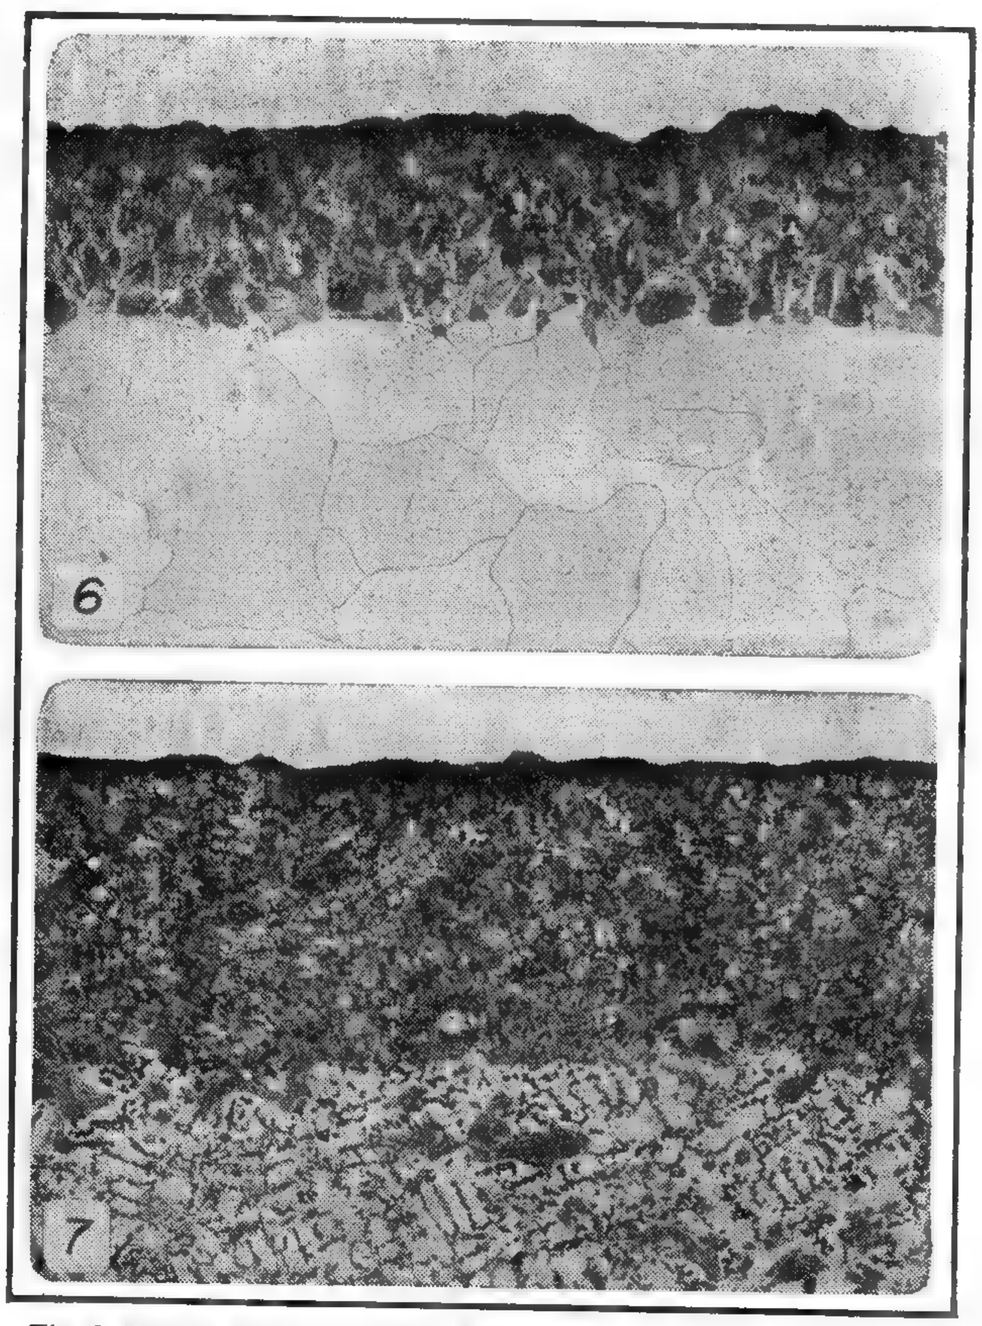

Fig. 6 Magnet iron containing 0.03% C, after carburizing at 1400 F for 5 hr. Etched with nital (× 100)

Fig. 7 White cast iron containing 3.5% C, after decarburizing for 2 hr and then carburizing for ■ hr at 1700 F. Etched with nital (× 100)

The Carburizing Reaction. The reaction involving the actual transfer of carbon occurs at the steel surface (interface) and the reactants, which are carbon compounds, may be considered independently. The interface reactions for two common carbon compounds, carbon monoxide and methane, may be written:

$$2CO = (C) + CO_2 \qquad (1)$$
$$CH_4 = (C) + 2H_2 \qquad (2)$$

where the symbol (C) represents the carbon dissolved in iron at the steel surface. Considering the reactions that occur for the same compounds, away from the interface, the reactions for deposition of carbon are expressed:

$$2CO = CO_2 + C \text{ (solid carbon)} \qquad (3)$$
$$CH_4 = 2H_2 + C \text{ (solid carbon)} \qquad (4)$$

These reactions may be compared from the viewpoint of the availability of carbon for the interface reactions (1 and 2) and of the stability of the carbon compounds at elevated temperatures (3 and 4). Figure 8 represents the equilibrium percentages of the gaseous reactants and products for saturated austenite, and for surface concentrations representing one-half the saturated value for a given steel at the temperatures illustrated. The curves for the decomposition reactions can be considered identical with those for saturated austenite (Curve *A*). For the gas dilution assumed, where the total volume of the gas reactant and gas product is taken as 20% of the total volume of gases, and where the total pressure is one atmosphere, it will be noted that the decomposition of methane is almost complete at equilibrium. Thus the carbon available for transfer from methane at the interface will be high. Carbon monoxide, on the contrary, is very stable and becomes increasingly so as the temperature and degree of dilution increase. The availability of carbon in this gas, under the conditions noted above, will be extremely low.

Equilibrium data may also be used to evaluate capacities for decarburization. Since CO is a very stable gas at high temperatures and high dilution, the presence of CO_2, even in small amounts, requires such a high percentage of CO for equilibrium that CO_2 may be called a strong decarburizing gas. Similarly, hydrogen may be considered a neutral gas or, when present in very large amounts, a weak decarburizing component.

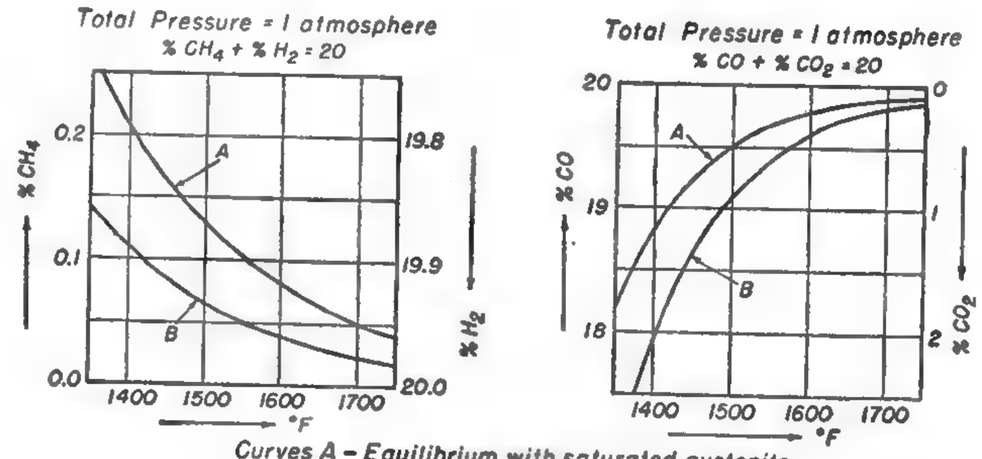

Fig. 8 Equilibrium relations for CH_4-H_2 and CO-CO_2

Intermediate reactions may occur that influence the carbon supply. For gaseous mediums, the concentration of hydrogen is important in re-forming carbon dioxide:

$$H_2 + CO_2 = CO + H_2O$$

For solid carburizers, an important reaction is

$$C \text{ (in charcoal)} + CO_2 = 2CO$$

Liquid carburizing may be aided by the reaction

$$2NaCN + BaCl_2 = Ba(CN)_2 + 2NaCl$$

These reactions illustrate the formation of carbon compounds for the actual transfer reactions at the interface.

The rate at which reactions proceed and the conditions that affect the speed of reaction must be considered in the practical application of equilibrium data. The equilibrium data are invaluable, however, in determining the point beyond which a reaction may not proceed.

Gas Carburizing. Gas carburizing practice consists in furnishing a continuous flow of prepared gases to the reaction chamber. The principal carburizing agent is generally a hydrocarbon and, as has been shown, gases of this type are relatively unstable. The use of ■ carrier gas of high stability permits the requirements for purging and the conditions of pressure to be maintained without deposition of soot. The hydrocarbon addition can then be varied at will to suit the demands of the steel charge for carbon. Typical reactions are discussed in preceding paragraphs.

Pack Carburizing. In contrast with gas carburizing, where the flow of gas is continuous, carbon dioxide, the gaseous product of the interface reaction between carburizing compound and steel, is changed in the container itself to the carburizing component, carbon monoxide. The rate at which carbon dioxide may be re-formed is one of the controlling factors of this process. Although the choice of carbonate energizers may alter the rate at which carbon

may be supplied at the interface, the flexibility of pack carburizing is small compared with that of gas carburizing.

Liquid Carburizing. Fused salts depend on cyanides for the supply of carbon; the common form of addition is sodium cyanide, NaCN. Barium chloride forms a percentage of the bath content. The postulated reactions at the interface are concerned with sodium cyanate, NaCNO, and barium cyanide $Ba(CN)_2$, both of which are formed from sodium cyanide by interaction with the oxygen of the air and with barium chloride, respectively. The decomposition products include $NaCO_3$, NaCl and $BaCN_2$. In addition to carbon, nitrogen is supplied to the steel surface, although the percentage of nitrogen added is low at temperatures above 1550 F.

Carbonitriding. Ammonia is added to carburizing gases for carbonitriding. The decomposition of ammonia is written:

$$NH_3 = \tfrac{1}{2}N_2 + 3/2H_2;$$

and the interface reaction for nitrogen supply, such as

$$NH_3 = (N) + 3/2H_2$$

where (N) represents nitrogen dissolved in iron, must occur before this decomposition. There is considerable evidence that a reaction between NH_3 and the carburizing gas components may evolve HCN, which is much more stable than ammonia at high temperatures. Only a small percentage of the nitrogen furnished by ammonia finds its way to the steel surface, and the nitrogen concentrations in the case are very low, although metallurgically effective.

General Comments. The investigation of Wells and Mehl[4] on the diffusion rates of carbon in austenite is of interest in connection with the mechanism described above. This investigation demonstrates that, in steel, factors such as the common alloying elements (in small quantities) and grain size have no perceptible influence on diffusion coefficients. The method by which these facts were established has the advantage of being independent of artificial mediums of supply.

The confirmation of these findings by carburizing experiments requires only that the conditions of supply be sufficient. That the mechanism of the flow of carbon in steel is one of solid diffusion seems incontestable. The formulation may thus be made without simultaneously considering mediums of supply.

Undoubtedly the ideal conditions for mediums of supply should permit no reactions at the interface except those directly concerned with the supply of carbon. Perhaps many of the anomalies reported in technical publications have resulted from factors of supply that are incapable of exact analysis.

A study of combustion reactions will demonstrate the complexity of intermediate and chain-forming components that are possible before stable products are formed. Similar possibilities exist when oxidizing elements (carbon dioxide and water vapor, for example) react at the interface with carbon-rich components. The exact role of such side reactions needs further investigation.

The phenomenon of surface concentrations in excess of saturated solubilities is reported too often to be disregarded. Various explanations have been reviewed recently.[7]

The numerous and varied investigations of R. W. Schlumph on carburizing practice, and the previous edition of this article by him, have contributed much to the present paper.

Selection of Carburizing Steel, Case Depth and Heat Treatment

By Gordon T. Williams*

A GREAT variety of types of steel may be used for the production of case carburized parts requiring a hard, wear-resistant or fatigue-resistant surface, supported by a tougher, more ductile core.

The following two basic factors must be considered first when selecting a steel for use in the carburizing process: (*a*) the quenching medium to be used for hardening after carburizing, as demanded by sections, shape, and distortion limits; (*b*) the type and degree of stresses to which the finished part will be subjected. Other considerations, such as availability, shop performance, and equipment, may further influence the choice. Since these are also the factors that will determine the heat treatment to be used, obviously steel and treatment must be considered simultaneously.

Quenching Medium. The quenching medium best adapted to a carburized part is ordinarily rather easily determined. Water or aqueous solutions are preferred because of the low first cost, the high rate of cooling, and the ease of cleaning parts subsequently. Such coolants are used wherever simple shapes or massive sections permit. When sections are thin, so that cracking or warping is probable, and when accurate contours must be preserved, as in gears, a medium that provides a slower cooling rate (usually oil) must be used. From such considerations, a decision can be made concerning the hardenability required and permitted in the steel.

The quenching medium must be one that will produce the desired hardness of the carburized surface, and also, in many instances, the required hardness and strength of the core at some depth below the surface. The critical cooling velocity of the steel is, of course, the controlling factor here. If maximum surface hardness is the only requirement, low-carbon steel with no alloying elements or with only small amounts of alloying elements, should be selected, to be quenched in water or, better, in an aqueous solution.* However, if too much distortion would result from so drastic a quench, or if the steel is likely to crack, then oil should be used, and a suitable alloy steel should be selected on the basis of necessary hardenability, so that the lower cooling velocity provided by oil will still be greater than the critical rate for the steel. Martempering (that is, quenching the steel in a salt bath maintained at a temperature above M_s, and then cooling the metal in air) is frequently advantageous in reducing distortion.

Stress Considerations. The type and magnitude of stresses to which the finished part will be subjected, indicate the mechanical properties demanded in the core, as well as the preferred metallographic character of the case and the depth of case. Static compressive loads normal to the surface require only sufficient depth of case and hardness of core to prevent the case from deforming when stressed. A case too shallow or core too weak will result in surface deformation under the load. This type of failure is often called "brinelling" because of similarity to the effect of Brinell testing of a hardened case. Abrasion of the case hardened surface will usually be resisted best by

* Materials Engineer, Pratt & Whitney Aircraft, East Hartford, Conn.

Prepared for the Subcommittee on Carburizing

* See the article "Quenching Mediums", page 615.

a case of maximum hardness, with low content of austenite to resist flowing under the load, and with sufficient depth to give reasonable life in wear. However, wear is of several types, and there are many exceptions to the above statement. The case selected should be of the type that will best resist the specific kind of abrasion encountered. For instance, for sliding (abrasive) loads, highest mineralogical (or indentation) hardness is preferred; for impact-wear loads, when some metal flow can be tolerated, a partially austenitic case is acceptable.

When bending stresses are to be encountered, the factors of core hardness and case depth are so closely related that they must be considered simultaneously, as the following discussion shows. Since stress in a beam is proportional to distance from the neutral axis, maximum resistance to stress is required at the surface. Higher resistance is readily provided by the presence of a hard, more fatigue-resistant case. In the absence of residual stresses, the effect of the case would be geometrically predictable, and it would be necessary only that sufficient case depth or core hardness be present so that the stress resistance at all points from neutral axis to surface would be greater than the proportionate stress. However, it has been shown[1] that the situation is more complicated because the hardened case is in compression resulting from its greater tendency to expand during the hardening transformation and from the resistance of the core to this

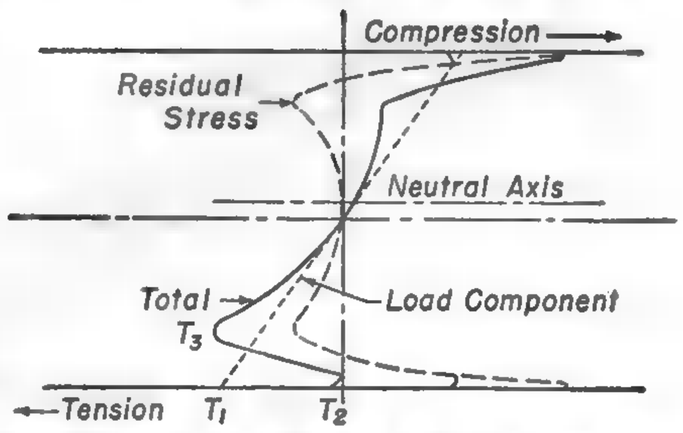

Fig. 1 Stress diagram for a loaded prestressed beam with conditions as in a case hardened piece (Almen[1])

expansion; also because the surface, even if ideally finished, carries a higher increment of stress than the simple-beam diagram would indicate, merely because it is a surface. Thus the actual situation will probably be about as shown in Fig. 1, according to Almen.[1] The residual stress (with no applied load) is shown by the broken line; a compressive stress exists in the surface, with a balancing tensile stress immediately under the case. The distribution of an imposed static load is shown by the dotted line; the solid line indicates the total stress, including the increment in surface load mentioned above. It should be noted that the surface effect also displaces the neutral axis toward the compression side, resulting in a higher tensile load effect at T_2 and T_3. Since fatigue failures are believed to occur only as a result of tensile stresses, particular attention should be given to the high stress at T_2 at the inside of the case, where the strength decreases and the residual stress is changing sharply. An increase of case depth may not be advantageous,[2] because it may result in further enlargement of the subsurface tensile stress and in added displacement of the apparent neutral axis. The foregoing considerations apply to stress conditions in bending, which may be responsible for tension failures at the surface, such as may occur at the root of a gear tooth. For compressive loading at the surface (as in antifriction bearings or at the pitch line of gear teeth) a subsurface tensile component will cause failure by pitting if necessary resistance to this tensile load is not provided.

At equal hardness, the composition of the case has a minor effect on the strength; that is, alloying elements in the steel do not necessarily improve the strength of the case. It must be remembered that the surface, being very hard, is highly sensitive to notch effects and may be harmed severely by tool marks, sharp corners, or harsh grinding.[3]

Since the combination of case depth and core strength must be such that the service stress does not exceed the resistance at any given point, and increased case depth may not improve the over-all resistance, serious attention should be given to the strength characteristics of the core of the finished piece. Raising the core strength may be much more effective than increasing case depth, to protect against fatigue failures from compressive loading. On the other hand, increasing the core hardness and strength reduces the compressive stress that will be developed in the case and may, therefore, be detrimental to fatigue life in bending. Because mixed structures, resulting from incomplete hardening, have undesirable properties, the core should be fully hardened for the most severe services.

When such considerations apply, the steel to be used must be selected with care. Carbon content alone will not permit the development of high core properties—or even of uniform properties—except with high rates of quenching, as in thin sections drastically cooled. When a slower (oil) quench must be used, because of the need to avoid warpage, and when the cooling rate will be slow at best, because a section is large, a steel of sufficient hardenability must be selected. Since the percentage of alloying elements is reflected in the cost of the steel, and the more highly alloyed steels are ordinarily more difficult to process, both in machining and in heat treating operations, there is a continuing trend toward the use of moderately alloyed steels, with carbon content higher than the former range of 0.08 to 0.25%. For example, gears and other automotive parts are being made currently to withstand high stresses, by use of moderately alloyed steels with carbon content as great as 0.40%; often the case depth can be reduced in such parts.

However, when sections are large or vary widely, a steel of high hardenability may be demanded, a fairly large alloy content will be necessary to ensure full hardening of the core, and it will be necessary to restrict the maximum carbon content of the steel in order to avoid excessively high hardness of the core. This problem is important when uncarburized surfaces must be machined after hardening.

Selection of Steel

Plain Carbon Steels. In this class are the steels that contain only carbon (in addition to the usual percentages of such elements as silicon and manganese) or such small amounts of alloying elements that the critical cooling velocity of the carburized case is normally reached only by quenching in aqueous mediums. Carbon contents greater than 0.25% are used infrequently in standard practice because of the brittleness of such steels in the fully quenched core. Ordinarily the maximum core strength with adequate toughness is about 100,000 psi. Heat treatment is simple and easily controlled.

Moderately Alloyed Steels. Steels that contain from 1 to 2% total alloying elements (such as nickel, chromium, manganese, and molybdenum, in proper combination, in addition to carbon) usually have sufficient hardenability for maximum hardness to be attained by oil quenching, and desired core properties up to a tensile strength of 200,000 psi are obtainable with suitable toughness by proper selection of steel composition. Carbon content up to 0.40% may be specified to increase the core strength further; the alloying elements provide the required toughness and hardenability. The differences among the various types of alloy steels in this classification are difficult to demonstrate, being easily overshadowed by differences in processing technique and individual preferences.[4] The "triple-alloy" or NE steels, developed to meet an emergency shortage of alloying elements and to take full advantage of the residual alloy content, have been widely and successfully applied, particularly when selected on the basis of hardenability. Simple and accurate heat treating procedures have been established for these steels.

Highly Alloyed Steels. In some instances the sections and service requirements are such that a total of alloying elements of more than 2% must be used to give the desired properties in the core. The added elements are the same as above, but carbon content is held to 0.25% max, because of the high hardenability of these steels. Extreme core toughness and strength may be developed. With this class

of steels the core hardness may easily become excessive in thin sections or on uncarburized surfaces, unless the maximum carbon content is severely restricted. The cost of steel and of processing, limits the use of these highly alloyed steels. Probability of austenite retention in the hardened case necessitates special, sometimes elaborate, heat treating cycles.

Grain Size and Abnormality. Grain growth of a steel at the carburizing temperature has a marked effect on mechanical properties and distortion after subsequent hardening. Steels of grain size 5 or finer, when tested in accordance with ASTM E 19, Method (*a*) (the McQuaid-Ehn test), are almost invariably preferred and usually demanded. In a limited number of applications, the greater hardenability of the coarser-grained steels warrants the use of such steels in spite of increased distortion and reduced toughness. Abnormality often accompanies fine grain in the test for grain size. Although the cooling velocity for full hardening must be greater for an abnormal than for a normal steel of a given composition, the change in critical rate is marked only in plain carbon steels, for which a quenching solution of NaCl or NaOH is often required, in order to avoid soft spots. Therefore, "normal" steel is sometimes specified in the plain carbon types where, after water quenching, freedom from soft spots is required. A moderate increase in manganese content (for example, SAE 1022 instead of 1020) will reduce the probability of abnormality and will help to decrease the effect of it by providing improved hardenability. Specifications concerning normality are rarely used in the alloy steels. Abnormality, implying rapid spheroidization of carbides, may be definitely advantageous in avoiding residual networks of carbide after certain treatments, such as *A* and *B* of Fig. 2.

Selection of Case Depth

Case Depth. For ordinary engineering application, choice may be made from several combinations of case depth and steel composition. In accordance with the stress diagram (Fig. 1) an increase in core strength, accomplished by increasing alloy content or carbon content or both, permits a reduction in the depth of case required to resist bending stresses. Likewise, if compressive loading is to be resisted, an increase in core hardness will aid in giving a non-deforming case, as will increased case depth. For resistance

Table I. Typical Automotive Carburizing Applications and Requirements[a]

Depth of Case, inch	Typical Parts Made from Low-Carbon Steel	Surface Condition When Treated	Requirements	Typical Parts Made from Medium-Carbon Steel	Requirements
Less than 0.020	Push-rod balls Push-rod sockets Speedometer gears Shackle bolts Shifter forks Tie-rod ball studs Tie-rod ball-stud sockets	Finished before treatment except for possible polishing operation	High degree of wear resistance Clean surface after treatment	Transmission gears Transmission main shafts and synchronizer sleeves (Surface generally finished before treatment)	Maintain or increase carbon content of the surface for higher resistance to wear and to fatigue Resistance to high occasional or shock loading Clean surface after treatment
	Water-pump shafts	When nitrided, 0.0003 to 0.001 in. per side removed for maximum wear resistance			
0.020 to 0.040	Pitman-arm ball studs Intermediate steering-arm ball studs	Finished before treatment except for possible polishing operation	High degree of wear resistance Sufficient strength to withstand service loads Clean surface after treatment	Transmission gears Ring gears Drive pinions (Surface finished before treatment except for lapping operation)	Increase carbon content at surface for greater wear resistance, load carrying ability and fatigue resistance. Clean surface after treatment
	Steering-arm bushings Valve rocker arms Valve rocker-arm shafts Gear-shifter shafts Brake and clutch-pedal shafts Water-pump shafts	Generally semifinished before treatment and finish ground after treatment	Enough case to permit finish grinding and maintain high hardness for necessary wear resistance		
0.040 to 0.060	Ring gears Drive pinions Transmission gears Side gears Side pinions	Finished before treatment except for lapping operation	High wear resistance to resist sliding, rolling or friction of abrasive nature. Resistance to heavy crushing. Resistance to high alternate bending stresses.		
	Piston pins Steering-knuckle pins[a] Side-pinion axles[a] Reverse idler-gear shafts[a] Counter-gear shafts[a]	Semifinished before treatment Finish ground after treatment	Operated frequently in bronze bushings High wear resistance Resistance to relatively high unit loads that cause brinelling. Resistance to fairly high alternate bending stresses. King pins also require resistance to high instantaneous or shock loads		
	Roller bearings		Resistance to heavy rolling action		
More than 0.060	Camshafts[b]	Semifinished before treatment	High wear resistance. Resistance to shock. Resistance to relatively high unit loads with a rapid sliding action.		

For more severe service, as in trucks and busses, the depth of case for corresponding parts may be somewhat deeper and the general tendency is to change to a steel that permits better mechanical properties, especially in the core.

(a) More case than is actually necessary to satisfy service requirements is put on parts of such length as these in order to avoid the necessity for extremely accurate straightening before grinding.

(b) Carburize deeper than is necessary to satisfy service requirements in order to compensate for inaccuracies in machining that are caused by the length of these parts, and by distortion from heat treatment, and to ensure sufficient case for necessary hardness and wear resistance after grinding.

to abrasion only, service life will usually be proportional to case depth alone. Obviously, therefore, a wide range of case depths may be employed on any given part; consideration of over-all properties and manufacturing economy will determine the steel and case depth.

As shown by the time-penetration formula, the rate of increase in case depth decreases with the time at temperature. Since this means a continuously increasing cost per hour, specifications for case depth are held to a minimum so that the time required will not be excessive.

Increased case beyond the normal depth is expensive to attain, and should be specified only when demanded by service requirements. Heavy-duty gears, for example, are often made with case depth of 0.060 to 0.090 in. and parts that require long service under highly abrasive conditions may have cases as deep as ⅛ in. If much of the case is to be removed by grinding, obviously allowance must be made in carburizing. Removal of case by grinding

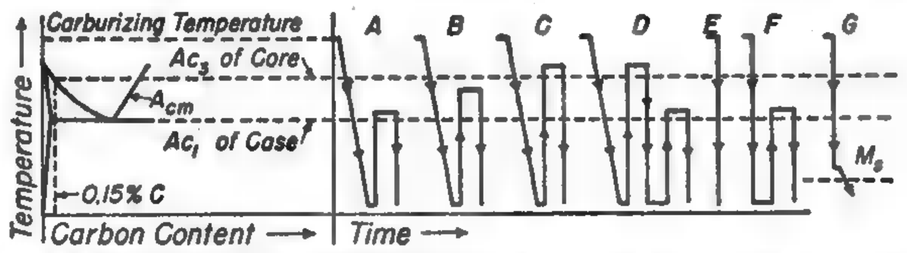

Fig. 2 Diagrammatic representation of various hardening treatments for carburized steels and summary of the properties of case and core; adequate hardenability is assumed.

Treatment	Case	Core
A (Best adapted to fine-grained steels)	Refined; excess carbide not dissolved.	Unrefined; soft and machinable.
B (Best adapted to fine-grained steels)	Slightly coarsened; some solution of excess carbide.	Partially refined; stronger than *A;* erratic.
C (Best adapted to fine-grained steels)	Somewhat coarsened; solution of excess carbide favored; austenite retention promoted in highly alloyed steels.	Refined; maximum core strength and hardness. Better combination of strength and ductility than *B.*
D (Best treatment for coarse-grained steels)	Refined; solution of excess carbide favored; austenite retention minimized.	Refined; soft and machinable; maximum toughness and resistance to impact.
E (Adapted to fine-grained steels only)	Unrefined with excess carbide dissolved; austenite retained; distortion minimized; fileproof when carbon content is high.	Fully hardened
F (Adapted to fine-grained steels only)	Refined; solution of excess carbide favored; austenite retention minimized.	Low hardness; high toughness.
G (Interrupted quench; martempering)	Unrefined with excess carbide dissolved; austenite retained; distortion minimized; filehard when carbon content is high.	Fully hardened.

should be held to a minimum, because of the high cost both of producing the case and of grinding it off; the serious danger of damaging the case by grinding-burns or grinding-cracks; and the fact that the outermost part of the case has the best resistance to wear. Grinding also reduces compressive stresses in the case, both by removal of the stressed layer and by thermal stress relief incidental to localized heating.

In connection with the selection of case depth, the maximum carbon content and thus the maximum actual hardness at the surface are relatively independent of case depth, as shown in the article on "Mechanism of Carburization", page 678. However, if the hardness test to be applied involves a heavy load with considerable penetration into the piece, a relatively deep case may be necessary to give a satisfactory result in the hardness test. For example, a high Rockwell C reading can be obtained only in cases that have a hard layer deeper than 0.025 in., yet a case only 0.005 in. deep may exhibit file hardness as great as that of the deeper cases. The readings obtained also depend on the support given to the case by the core. Allowance should be made for these factors in selecting test methods for use with lighter cases.

Table I, from Boegehold and Tobin,[3] summarizes typical applications and requirements.

Type of Case. For two reasons it may be desirable to avoid a hypereutectoid layer. First, if the pieee is cooled slowly from carburizing, proeutectoid cementite will be precipitated at the grain boundaries, usually forming a network. This will be redissolved during subsequent austenitizing, but slowly, especially if the carbides are complex, and only if heated above the required A_{cm} temperature. Residual grain-boundary cementite in the finished piece is a frequent cause for failure from brittleness, and is a common cause for checking or cracking during grinding. Second, even though direct quenching is employed and the separation of proeutectoid cementite is inhibited, the hypereutectoid carbon content will increase the amount of retained austenite. For most applications a martensitic case free from austenite is preferable. Consequently, if the steel is highly alloyed and thus susceptible to the retention of austenite, the carbon content of the case should be held to the lowest amount compatible with full hardness, usually eutectoid content. Limitation of maximum carbon content to less than 1.0% is very difficult in pack carburizing, and gaseous mediums are favored when a lower-carbon case is desired or required.

In certain applications, the presence of cementite in the case is a desirable aid in wear resistance. For such applications it is important that the carbon content be high while the excess carbides are preferably in spheroidal form.

Selection of Heat Treatment

A carburized piece must be regarded as a duplex material, that is, a high-carbon surface, and a low-carbon core, with a gradual transition from one to the other. Two critical temperatures are thus involved in hardening, and the excess carbide of the case may or may not be dissolved at the hardening temperature selected.

Figure 2 illustrates the requirements and summarizes the usual methods by which carburized work is heat treated.[5] Table II shows transformation temperatures and preferred treatments for the usual carburizing steels.

Annealing. The annealing temperature and method of cooling should be selected to provide the required machinability and necessary grain refinement. When machining operations are severe, and when best dimensional accuracy is required, the steel may be stress relieved between rough and finish machining.

Carburizing. The type and depth of case must be carefully controlled.[3,6] The temperature employed will usually be 1650 to 1700 F, to give a fair rate of penetration without increasing furnace costs unduly. When steels of higher carbon content are used (for example, 0.40% C) and a shallow case is desired, carburizing is often done at 1550 to 1600 F to give better control of case depth. Uniform temperatures must be provided in order to produce uniform carburizing and hardening, and to control distortion.

Cooling from Carburizing. Since steel is carburized above the transformation temperatures of case and core, obviously both case and core will harden if the piece is cooled from the carburizing operation at a rate faster than the critical cooling rate. Before the advent of steels controlled to have a fine grain size at carburizing temperatures, such "direct quenching" was useful only for parts of simple shape and section because of the danger of cracking and distortion. Coarse-grained steels, when directly quenched, often show objectionable brittleness, and a more complicated hardening treatment must be used. With fine-grained alloy steels and suitable equipment, it is usually preferable to quench directly in oil, since with this treatment distortion is lower and more regular than when parts are cooled slowly and then reheated for hardening. In handling pieces from the higher (carburizing) temperature and in the quantities delivered discontinuously from carburizing furnaces, more difficulty is involved than in reheating for hardening; consequently, the reheat-

(a) All steels preferably of grain size 5 or finer. (b) Ac_3 of core will decrease as carbon content is increased.
(c) Spheroidization of excess carbide by subcritical treatment before hardening may be used to decrease the amount of austenite retained.

ing procedure is sometimes preferred. A further handicap to the full use of direct quenching is the greater amount of retained austenite in the hardened case. The more highly alloyed steels can rarely be used in the direct-quenched condition for this reason, and many of the moderately alloyed steels retain so much austenite that the treatment is not acceptable, especially when finished parts will be subject to rolling under load (such as spiral or hypoid gears). Retention of austenite and distortion may both be decreased in direct quenching, by retarded cooling to a temperature close to Ar_1 before quenching. This may be accomplished by transferring the work pieces to a furnace held at a temperature just above Ar_1 and stabilizing the temperature of the steel at this level before quenching. Quenching from the carburizing temperature may be followed by reheating the steel above the Ac_1 temperature of the case to provide maximum refinement of the case, with a minimum amount of retained austenite. Direct quenching will give the highest attainable strength and hardness of the core with less than maximum toughness. The case will be file hard, but with more highly alloyed steels, may have a low indentation hardness because of the retention of austenite. This treatment will minimize the amount of grain-boundary cementite.

When machining operations must be performed on carburized surfaces after carburizing, the steel must be either slowly cooled or annealed. With steels of high hardenability, and with certain types of equipment, the available slow rate of cooling may still produce enough hardening so that subsequent softening is necessary. An intermediate cooling rate may be necessary in order to avoid the separation of carbide in network form. Decarburization may occur during slow cooling without suitable precautions.

Steel to be water quenched subsequently, may be either slowly cooled from the carburizing operation, or oil quenched to give some refinement to the core without danger of cracking or severe distortion.

Separate Hardening Treatments. As indicated in Fig. 2, various hardening treatments may be applied when steel is reheated after cooling from carburizing, depending on whether the case only or both case and core are to be hardened. For the more highly alloyed steels, the method is preferable that most nearly approaches direct quenching; that is, a single reheating to a temperature 25 to 50 F above the upper transformation point of the core (and thus, of course, also above the transformation range of the case). In this way, maximum core strength may be attained with good toughness, and nearly all the excess carbide in the case may be dissolved. Thus retention of austenite is probable in the more highly alloyed steels, although less than would result from direct quenching. Distortion will be higher than after direct quenching, but may be held within acceptable limits. This treatment, like direct quenching, is rarely applied to plain carbon steels.

Steels may be reheated to a temperature just above the transformation range of the case, either after slow cooling or after quenching from carburizing. If the steel is reheated after slow cooling, the core will be soft but only moderately tough because of the omission of any refining treatment; the case will be hard, but may be brittle because of undissolved carbide; distortion will be low because the core has not been quenched. However, if the work has been quenched directly from the carburizing temperature, a high degree of refinement will result from this combination of treatments. The core will be fully refined, having high toughness and low hardness; and the case will be fully hardened, with good toughness resulting from the absence of cementite as network; however, distortion will be considerable. Slow cooling from the carburizing temperature, then reheating and quenching from above the transformation temperature of the core, and finally quenching again from above the transformation range of the case, will give similar results but with maximum possible refinement, coupled with a high degree of distortion. Control of steels for grain-growth characteristics, together with the demand for high-strength cores and a realization of the futility of high toughness of core and high impact values, has made this treatment less used.

The steel may simply be reheated to a temperature well above the transformation range of the case, but below that of the core. With such hardening, the core is partially refined and the case is improved slightly because of partial solution of excess cementite. This is not recommended for critical applications.

For some applications, interrupted quenching treatments, such as martempering, may be useful in reducing distortion. Martempering consists of quenching the steel in a salt bath that is maintained at a temperature higher than the M_s point of the steel (500 to 700 F is the usual bath temperature) and then cooling in air. Since the cooling velocity provided by the salt bath is relatively low, a steel of relatively high hardenability is required, if case and core are to harden fully, but distortion will be low in comparison with that resulting from normal quenching.

Cold treatment, preceded and followed by tempering, may be useful for elimination of austenite and is frequently the only way to obtain high hardness readings from cases of high alloy content, particularly if the carbon content of the case is hypereutectoid.

Tempering. Residual stresses from quenching will be relieved somewhat, and resistance to cracking during grinding operations will be improved by reheating the hardened piece to the highest temperature (usually 275 to 350 F) that will not reduce appreciably the hardness and wear resistance of the case. The tempering treatment is frequently omitted. Some stress relief is obtained by any washing operation conducted at or near the temperature of boiling water.

Measurement of Case Depth

BY R. B. SCHENCK*

THE following discussion of case depth measurement is intended to apply to cases produced by carburizing, cyaniding, nitriding, carbonitriding, induction hardening and flame hardening. Case depth is usually determined either by direct measurement, by chemical analysis or by measurements of hardness. Other methods have been used but are not important enough to warrant discussion here.

Direct Measurement. This method, in its various modifications, is the one most commonly used. It can be applied to any type of case in the hardened state, and also, with certain limitations, to unhardened cases where a difference in composition distinguishes the case from the core.

Regardless of the process by which they are produced, all cases are characterized by a transition zone in which the case blends into the core. This blending of case and core may be so gradual that no sharp line of demarcation can be observed. The usual practice is to measure from the outer edge of the case to the line where the case ends, estimating as accurately as possible when the "end point" is indistinct.

The accuracy of measurement, as determined by the distinctness of this "end point", is influenced by a number of factors, such as composition of core, composition of case, previous heat treatment and method of preparing the sample. Differences in quenching temperature and the degree of hardening may influence the apparent case depth appreciably. A possible source of error is the angle at which the specimen is sectioned. It is essential that the measurement be along a line normal to the outer surface of the case.

The several methods employing direct measurement are:

Scale Measurement of Rough Fracture. This method is approximate only and should be standardized by scale measurements of a highly polished cross section by means of a high-power microscope. Carbon steel test plugs, water-quenched and properly standardized with the high-power microscope, are often helpful in checking cases in alloy steels that are difficult to measure.

This method applies only to cases in the hardened state and is usually limited to carburized cases. The measurement can be made either with the unaided eye and a suitably graduated steel scale (preferably in hundredths of an inch), or with a low-power microscope (× 10 to 15) containing a suitable scale. A Brinell microscope answers the purpose well. The fractured surface may be either untouched, etched or blued before measurement. Untouched fractures can be measured with fair accuracy when the core hardness is sufficiently low to provide good contrast between case and core. Hard cores usually require coloring by either etching or bluing. Etching is used extensively and produces good results; cold nital is the usual reagent. Bluing offers an effective method for producing the required contrast. Any means of heating may be employed that will develop the necessary temper colors.

Scale Measurement of Rough-Polished Cross Section. Of the various methods involving direct measurement, this is the one most extensively used; it is considered more accurate and dependable than measurement of rough fracture. As mentioned above, standardization with the microscope and the use of carbon steel test plugs are recommended for increased accuracy.

Although approximate results can frequently be obtained in measurement of unhardened cases, the use of this method is generally confined to cases in the hardened state. The required contrast may be developed by etching, bluing or shot blasting. Etching is the usual method.

Scale Measurement of Highly Polished Cross Section, Using High-Power Microscope. Both hardened and unhardened cases can be measured by this method with a high degree of accuracy. This is essentially a laboratory method and requires trained personnel. Magnifications of × 100, made by using an eyepiece equipped with a scale graduated in thousandths of an inch, are suitable for a wide variety of work. Either cold nital or cold picral is the usual etching reagent. This method provides greater accuracy than measurement either of rough fracture or of rough-polished cross section, especially where it is desired to measure the individual zones, or where it is difficult to develop the necessary contrasts.

Chemical Analysis. Successive layers are machined from the surface and subjected to chemical analysis in this method, which can be applied only where the case is machinable and different in composition from the core, as in work that has been slowly cooled or quenched and tempered after carburizing. This is strictly a laboratory method, slow and costly. The chief value of it is in research work and in control of case composition.

Hardness Measurements. This method applies only to cases in the hardened state. The sample may be either taper-ground, step-ground or sectioned in a plane normal to the surface. A series of hardness measurements (a traverse) is then made across the section by means of a suitable indentation test. This is primarily a laboratory method and requires the utmost precision if dependable results are to be expected. The accuracy decreases as the case depth decreases. The preparation of the taper-ground and the step-ground specimens is more exacting, but the readings can be more accurately spaced than with the samples sectioned normal to the surface. On the other hand, the readings from the taper-ground and step-ground samples are subject to error because of the effect of the softer underlying metal. In spite of the difficulties just mentioned, the various modifications of this method are coming into more extended use. The main application in the past has been in research work. Recently the use of hardness measurements has been extended to production control. Large quantities of nitrided work have been produced under specifications calling for minimum hardnesses at the surface and at a given depth. Both taper-grinding and step-grinding have been used for this purpose.

Pack Carburizing

BY H. W. MCQUAID*

WHEN solid carburizers are used, carbon is formed on the surface of steel by the decomposition of carbon monoxide into carbon and carbon dioxide. The carbon dioxide that is formed reacts immediately with the incandescent carbon in the compound to produce fresh carbon monoxide. This process is repeated as long as there is enough carbon present to react with the excess of carbon dioxide. The decomposition of carbon monoxide occurs at the surface of the steel, which must be at such a temperature that the carbon formed will dissolve in the steel.

* Metallurgical Consultant, Cleveland

Prepared for the Subcommittee on Carburizing.

Carburizing Compounds. The usual commercial carburizing compound contains a mixture of approximately 20% alkali or other metal carbonates bound to a hardwood charcoal by oil, tar or molasses. This carbonate energizer is generally in the form of barium carbonate with occasionally a small percentage of sodium and calcium carbonates. Approximately 20% of coke is usually added as a diluent. The presence of the coke increases the rate of transfer of heat through the compound and hence is valuable in obtaining uniform temperatures.

Because of the loss of the carbonate energizer, the powdering of the compound and the burning in service, new

compound must be added before the carburizer is used again. It is necessary to have approximately 8% of the carbonate energizer present in the mixed compound. A percentage greater than this has little effect on the rate of carburization, whereas a decrease in the amount of energizer to less than 8% retards the carburizing action and decreases the maximum carbon content of the surface. The addition of new compound will vary according to the care used in handling, the amount of direct quenching that is done, and the type of binder used in the compound. If care is taken in the selection of boxes and the handling of the compound, it is possible in most plants to utilize at least five parts of old compound with one part of new, and some plants are operating with even smaller additions of new compound. In many plants, however, the conditions are such that more new compound is required and it is not unusual for plants to make an addition of one part of new compound to three parts of used compound.

Several carburizing compounds available do not consist essentially of charcoal coated with a carbonate energizer. Carburizing compounds have been made from various combinations of organic materials, such as charred leather, burned bone, raw bone, or bone with charcoal. When applied properly, these compounds will give satisfactory results. However, they are relatively expensive and if no energizer is used, the carburizing action is slow. Large quantities of bone-black compound containing a comparatively low percentage of energizer have been used for applications where low-carbon cases are desirable. Large quantities of a carburizing compound have also been used, consisting of very dense charcoal impregnated with a water-soluble energizer; these compounds will usually give satisfactory results. Some compounds on the market vary greatly from the standard by substitution of a special type of coke for charcoal. Other compounds that have been developed do not use a carbonate type of energizer.

Special compounds have been developed to resist burning when in contact with air at carburizing temperatures. These compounds usually have a binder in which the energizer is mixed before coating and the material is preheated to incandescence during manufacture. Compounds of this type are important in operations where work is quenched directly from the carburizing box.

Selection of Carburizing Compound. In the selection of a carburizing compound, many factors should be considered. The handling equipment is important as well as the quenching methods. When the work pieces are cooled in a well-designed box where the compound is not subject to exposure to air while at red heat, it is not necessary to give much consideration to the burning characteristics. Where there is much quenching from the box, the rate of burning is an important economic factor and should be considered in selecting a compound.

Since the amount of new compound to be used is determined by the amount of energizer retained in the used compound, the method of incorporating the energizer is important. The cost of a compound should be based on the number of pounds of steel that can be satisfactorily carburized per pound of compound.

The coated compound is at a disadvantage when compared with the impregnated compound, except where handling and cooling conditions are exceptionally favorable. However, if no attempt is made to take advantage of a more stable compound by increasing the ratio of used compound to new, then the more expensive compound is of little advantage.

Packing. The packing of pieces in a compound is a dusty and disagreeable operation. For this reason the grouping of boxes, work pieces and compound should be carefully planned so that the compound will require a minimum of handling. The work pieces should come to the packer, if possible, already stacked and sorted, preferably on open trays or in pans.

A layer of compound is first put into the empty box. This layer should be approximately 1 in. deep, although with lighter work pieces the depth can be reduced to ½ in. The amount of compound that is used should be kept to a minimum, which depends on the design of the box and the type of piece. If the boxes are warped badly, more compound must be placed on the top to prevent exposure of the steel by burning away of the compound. Ordinarily with alloy boxes much less compound is required than is commonly used. The compound is an excellent heat insulator; the metal is a very good conductor. Therefore, if the amount of compound is increased to even a little more than the minimum necessary to support the work material, an immediate and important increase in heating time will result. An increase of ½ in. in the compound between the work pieces and the wall of the box is equivalent to increasing the wall thickness of the box by many inches.

It is the usual practice to remove the dust and fine particles by screening, and between rough handling and the screening a large percentage of energizer and charcoal is wasted. The ordinary coated charcoal compound is extremely friable and must be handled with great care. If due attention is given to this problem the amount of compound used can be greatly reduced. Some of the conveyers, storage arrangements, and cleaning devices destroy so much carburizing compound that they become a liability rather than an asset.

Boxes for Carburizing. Heat-resistant alloy boxes have become quite standard, but there are still many applications where rolled steel or cast steel boxes have an advantage. The heat-resistant boxes are usually made from a nickel-chromium alloy. The heat-resistant alloy can be obtained either as sheet or as a casting. Each type has its advocates. The cast form is generally the less expensive, especially where boxes are of a nonsymmetrical design. It is possible to obtain the cast boxes with a wall thickness that compares favorably with that of rolled sheets; consequently there has been a general tendency toward reduction in thickness of the walls of cast carburizing containers. The sheet alloy boxes, ordinarily used for cylindrical shapes, prove quite successful in this application, provided the welding is properly done. Poor welding has caused a large percentage of the failures that have occurred in the use of sheet alloy boxes.

Before a decision that heat-resistant alloys are to be employed for carburizing boxes, the services expected from the containers should be thoroughly investigated. For boxes that are used infrequently, especially where the type of work piece to be carburized is large and nonsymmetrical in section, cast steel or welded steel plate often proves more economical than the much more costly alloy boxes. As a rule, however, where boxes are frequently used and the shape and size of the pieces do not require excessively large boxes, the best heat-resistant alloy will prove economical.

The design of the box* and the method of packing will influence the results of carburizing.

Whenever possible, pieces should be packed with their longest dimension vertical. This requirement is important for shafts and stem pinions. Vertical packing permits vertical quenching with the least tendency of the tongs to distort the hot steel.

Uniform heating is important, and therefore a cylindrical box is to be preferred to rectangular boxes, in which the corners heat at a different rate from the sides, and where the pieces in the corners come to temperature before pieces in the center. Center tubes should be used wherever possible. These can be designed as integral with the box or as separate parts, depending on whether or not they must be removed to facilitate handling the work pieces.

Temperatures for Carburizing and Depth of Case. For steels of the fine-grained type, a carburizing temperature between 1675 and 1700 F will be satisfactory. However, many carburizing furnaces operate at 1725 F or even 1750 F with good results; these are usually continuous furnaces with carefully controlled cycles.

To reduce the concentration of carbon on the surface of some steels, especially the higher-nickel alloy steels, lower carburizing temperatures are employed (1625 to 1650 F). The same temperature is used in some plants to reduce warpage to a minimum. For pieces that have a small section where the case depth must be controlled to a maximum of a few thousandths of an inch still lower carburizing temperatures are employed, and in some applications 1550 F is used with a bone-base compound low in energizer.

* R. W. Rousch and A. C. Dames, A Study of Commercial Carburizing Containers, Trans ASM 26, 646 (1938)

Even with the best of furnaces and practice at 1700 F, it is difficult to obtain a case depth that has a total variation of less than 0.010 in. from maximum to minimum in a given furnace load. Pack carburizing has disadvantages if a case less than 0.025 in. deep is to be produced, unless boxes are properly designed and pieces are efficiently packed to minimize variation in temperature. With the standard practice of today, case depths of less than 0.025 in. should not be specified for pack carburizing.

It is difficult to control the maximum carbon content in the case of a pack carburized part. In pack carburizing, the rate of evolution of carburizing gas is fixed and is virtually always in excess of the amount required to supply the necessary carbon for ■ saturated surface, so in this process it is customary to obtain ■ saturated outside surface layer. If the energizer is deliberately controlled to reduce the carburizing effect (and ordinarily none but a bone compound can be controlled easily), it is possible to obtain cases of lower carbon content than the maximum that would be obtained under ordinary conditions at the carburizing temperature. The total carbon content in excess of the eutectoid composition will be greater as the carburizing temperature increases, because the solubility of carbon in austenite increases with increasing temperature.

Furnaces for Pack Carburizing. The fundamental requirement of pack carburizing is the control of variables that affect the temperature of the steel. The first problem is to secure a furnace that can be controlled within plus or minus 10 F, heating uniformly throughout within 20 F.

Many of the so-called "standard" box-type furnaces on the market, especially those built for oil fuel, are unsuitable for carburizing because of the great variation in temperature from one point to another. This type of furnace is likely to have a low temperature near the door and a high temperature at the back. Compensation is often arranged by placing in the back of the furnace the pieces requiring a deep case, and placing in the front the pieces requiring a lighter case.

Where the volume of production will permit, a pusher type of continuous furnace is desirable. The economic justification for this type of furnace is closely related to the design of the boxes and to the depth of case required. Where case depth is not too great and where boxes are designed to reduce the heating time to ■ minimum, the continuous pusher type of furnace has many applications. With careful attention to box design, the depth of case can be held to reasonably close limits, even though the pieces differ greatly in size. Careful attention is required in order to approach uniformity of steel temperature at approximately 1500 F, at which temperature the carburizing rate is low. When a minimum of compound is used, the over-all carburizing time can be reduced and a wide range of commercial pieces can be carburized to a depth of 0.040 to 0.050 in. in 4 hr at 1700 F.

Pusher furnaces are designed to have the exit end of the furnace at the carburizing temperature to facilitate quenching from the carburizing furnace and also to permit air cooling of the box, which is sometimes desirable. At one time counterflow furnaces were employed, designed to utilize the high heat content of the finished pieces in preheating the cold steel moving in the opposite direction. These furnaces were considered desirable because of the great economy of fuel, especially when electrically heated. It was found, however, that the very slow cooling of the heated pieces—especially at temperatures higher than 1000 F—was detrimental to good case hardening, because of decarburization. A continuous pusher furnace should allow approximately 50% more production than a batch-type furnace that has the same clear hearth area of 16 sq ft.

The continuous furnace will produce more uniformly carburized pieces, with lower cost of fuel and container. The actual cost depends on the design of the container and the heating characteristics of the continuous furnace.

Rotary retorts like those used for gas carburizing are sometimes used with compound. This operation is most satisfactory for small pieces, because they are continually agitated during the slow rotation of the horizontal retort. With large quantities of small pieces, the movement insures good contact with the compound, which acts not only to furnish carbon but also to cushion and protect the steel. The ease of loading and unloading facilitates the carburizing of small parts when the rotary retort is used.

Gas Carburizing

By J. A. Dow*

IN GAS CARBURIZING, the carbon of the furnace atmosphere is in the form of gaseous hydrocarbon compounds or carbon monoxide. In order to transfer the carbon to the steel, the gaseous compounds must react with the steel on the surface or in the immediate subsurface of the work.

The chemical reactions involved can be exemplified by the following equations:

$$CH_4 \rightleftarrows (C) + 2H_2 \quad (1)$$

$$C_2H_6 \rightleftarrows (C) + XCH_4 + YH_2 \quad (2)$$

$$C_3H_8 \rightleftarrows (C) + XC_2H_6 + YCH_4 + ZH_2 \quad (3)$$

$$2CO \rightleftarrows (C) + CO_2 \quad (4)$$

$$CO + H_2 \rightleftarrows (C) + H_2O \quad (5)$$

where (C) is carbon dissolved in austenite.

For an understanding of the part that each of the above reactions plays in gas carburizing, the reactions must be studied not only with regard to the weight of carbon available per unit volume of the reactants, but also with regard to the concentration of reactant that must be maintained in the gas surrounding the steel, if carbon is to be supplied to the steel at the desired rate.

A measure of the weight of carbon available per unit volume of reactant, is indicated by a study of the equilibriums of the five reactions at carburizing temperatures. The equilibrium data required for this work have been obtained largely by experiment, and by the use of the principles of thermodynamics expounded by Lewis and Randall.[1] The results of a study of reactions (1) and (4), based on equilibrium constants, appear on page 678 of this Handbook. The figures on the available carbon in CO and CH_4 are based on the assumption that reactions (1) and (4) proceed until they are in equilibrium with the austenite of the surface of the steel. However, hundreds of analyses of the atmosphere surrounding the work pieces in commercial furnaces for gas carburizing show that the concentration of CH_4 in an atmosphere must be many times the concentration that would be in equilibrium with saturated austenite, in order to carburize at a commercially acceptable rate and to produce the desired surface carbon content. Laboratory experiments* that were made with gas mixtures treated for the removal of hydrocarbons heavier than CH_4, further substantiate this. In none of these experiments was a saturated austenite case produced in four hours or less at 1700 F by a gas mixture free from decarburizing agents, and containing as high as 250 times the concentration of CH_4 for equilibrium with saturated austenite. Carbon contents closely approaching saturation were, however, formed in a 16-hr test.

In contrast with the experimental data above, experience indicates that reactions (4) and (5) are very rapid; that a carbon monoxide atmosphere quickly brings the surface

* Private communications from H. J. Hammond and M. R. Larson

of the steel to a carbon content almost in equilibrium with the atmosphere, or will itself change rapidly in composition until the gas mixture and the steel surface come close to meeting equilibrium requirements.

It may therefore be concluded that the rate of the reaction involved must also be considered before the amount of carbon available for carburizing in a reactant gas can be calculated with assurance; and that the degree of advancement that the reactions can attain, as shown by their equilibrium constants, is no indication of their relative reaction rates.

The rate at which carbon diffuses into steel, and the factors governing this rate, are discussed in this Handbook on page 678, and in greater detail elsewhere.[2] It should be noted that this rate is a variable, much faster in the early part of a carburizing cycle than in the later stages; and since the rate at which carbon is supplied to the steel by the reactions indicated above, must be related to this varying rate of diffusion, the subject of gas carburizing must be primarily a study of the rates of the reactions involved.

Factors Influencing Gas Carburizing. In the absence of more definite data, the following observations or comparisons will be of value toward an understanding of the reactions listed above. Such an understanding is necessary for intelligent control of gas carburizing.

1 Effect of Time. When a constant surface carbon content is maintained, the demand of the steel for carbon varies inversely as the square root of the elapsed time of the cycle (*see* page 679 of this Handbook). It follows from this and the discussion above, that when carburizing with CH_4 it is necessary to reduce the concentration of the CH_4, as the cycle progresses, leaving just enough to satisfy the demand of the steel for carbon, if the most desirable operating conditions are to be attained. In practice, when carburizing to saturated cases, the atmosphere is usually too weak to produce a saturated austenite surface the first few minutes at operating temperature, and is more concentrated than necessary in the later stages.

2 Source of Carbon. In all commercial atmospheres used today for gas carburizing, two or more hydrocarbons react with the steel, supplying it with carbon. Although the source of carbon may be a pure propane, other hydrocarbons, principally methane, will be formed in the initial pyrolysis of the propane and can themselves add carbon to the steel; and all natural gases contain appreciable percentages of hydrocarbons heavier than methane.

3 Hydrocarbons. The hydrocarbons encountered in gas carburizing atmospheres can be classified in three groups, in terms of their relative rate of breakdown when exposed to surfaces at carburizing temperatures.

Group I methane
Group II ethane and propane
Group III oil vapors

The gases in groups II and III apparently break down, at carburizing temperatures, from 30 to 300 times as fast as CH_4, when present in equal concentrations.[3]

4 Hydrogen Concentration. An atmosphere containing just enough methane to be in equilibrium with saturated austenite, will quickly carburize an infinitely thin piece of steel (in which diffusion of carbon from the surface does not take place) to a carbon content closely approaching saturation. From the definition of the equilibrium constant of reaction (1), namely, $K = (CH_4)/(H_2)^2$, the concentration of methane in such an atmosphere may vary over a wide range and is proportional to the square of the hydrogen content of the atmosphere.

To illustrate, an atmosphere containing 0.05% CH_4 and 19.95% H_2 would be in equilibrium with saturated austenite at 1700 F (*see* curve, page 680 of this Handbook), whereas in an atmosphere with only 2% H_2 this same methane content would be almost 100 times the concentration for equilibrium with saturated austenite. In spite of equal methane concentrations, the latter atmosphere has the necessary potential to supply carbon many times as fast as the first atmosphere, to a steel part being carburized and whose surface composition approaches saturated austenite.

It may be for this reason that the major part of the carbon of hydrocarbons supplied to a furnace seems to enter the steel if the hydrogen content of the furnace atmosphere is low; whereas by comparison between the compositions of input and effluent gases, less than 30% of the calculated available carbon is generally usable in atmospheres containing 40 to 50% H_2. The remainder leaves the furnace as undecomposed hydrocarbon. This undecomposed hydrocarbon serves as a reservoir of carbon that may be drawn on if the furnace load is increased, with a lesser sacrifice in the surface carbon content of the case produced than if the effluent gas were very low in hydrocarbon—a condition that has been reported with low-hydrogen atmospheres.

5 Methane Content. Measurements of the methane content of a furnace atmosphere can readily be made by conventional methods of gas analysis and are generally used along with measurements of case depth to control the operation of continuous furnaces. From the above discussion (1) the demand of steel for carbon as a function of the length of the carburizing cycle, (2) the ethane and propane content of the gas supply, and (3) the hydrogen content of the furnace atmosphere, all affect the methane concentration required to produce a result. Other factors, such as rapidity of circulation of the atmosphere, the amount of free space in the furnace load, sulfur content of the atmosphere, probably also affect the required methane concentration. For this reason, comparisons of the methane concentration required in two different furnaces cannot by themselves mean much, but in any single furnace if certain conditions outlined below under Furnace Operation are met, methane determinations are quite satisfactory as an indication of the carburizing activity of the atmosphere.

Analyses of gas samples from a continuous furnace usually show some variation in the methane content in different parts of the furnace; but by extreme means only, if at all, can the methane content be made to vary enough to maintain the same surface carbon content on parts in the various zones as the parts progress through the furnace. In contrast, the hydrocarbons of Group II, with a lower diffusion rate and a much higher rate of breakdown, should be more readily usable to vary the carburizing activity of the atmosphere throughout a furnace so as to satisfy the demand of the steel for carbon.

In any given furnace, the methane content of the atmosphere required to produce a certain desired surface carbon content of case, less than saturation, seems to vary approximately as the square of the fractional degree of saturation of the desired case. For this reason the operation of a continuous furnace to produce cases of less than saturated carbon content and within commercial tolerances, is not too difficult and the operation is not particularly sensitive to minor variations in loading.

6 Overactive Atmospheres. Carburizing atmospheres may be considerably more active than is required to maintain a saturated case and still not deposit soot in detrimental quantities on the surface of parts that are being carburized. However, these overactive atmospheres can carburize to carbon contents, at the surface, that are well above saturation values, a phenomenon particularly noticeable with certain steels. Naturally, these highly active atmospheres permit considerable variation in concentration throughout a furnace, with no noticeable effect on the uniformity of the case, and are particularly good in penetrating blind holes and crevices.

7 Effect of Carbon Monoxide. In contrast with methane pyrolysis, the reactions represented by equations (4) and (5) above have very high rates, and will quickly carburize or decarburize a part, or the system will adjust itself by change in reactant concentration until the atmosphere and the surface layer of the part closely approach equilibrium conditions. In fact, if reactions (4) and (5) are on the decarburizing side, they determine the effect of an atmosphere, even though it has a high methane content.

8 Sampling for Analysis of the Gas. Obtaining representative samples of the atmosphere surrounding parts that are being treated is quite easy for the determination of compounds that react slowly—methane, for example—but can be almost impossible for quickly reacting substances such as carbon dioxide and water vapor. The amount of these quickly reacting gases contained in the atmosphere at the surface of the steel may be quite differ-

ent from the amount in any open spot where a sample can be taken. Rapid circulation of the furnace atmosphere will reduce the amount of error in sampling.

9 Sulfur. Sulfur compounds in the furnace atmosphere, in some manner greatly reduce the carburizing activity of the hydrocarbons. Even extremely high concentrations of hydrocarbon may produce cases of 0.6 to 0.8% C max with sulfur present in any quantity, and the depth of hardenable case produced in a given time is reduced along with the reduction in surface carbon content. Less soot is deposited in the furnace than would be expected. Traces of sulfur are not apparently injurious but sufficient data are not available to set a top safe limit.

The sulfur is apparently present, in the furnace itself, almost entirely as organic compounds probably in equilibrium with small percentages of H_2S. Lead acetate checks for H_2S have not proved a very satisfactory indication of the total sulfur content of the gas.

Sulfur can also be the cause of early failure of the alloy fixtures used for handling the work in the furnace.

Diluting Gases. Diluting gases serve three purposes in all gas carburizing: first, to avoid an excessively concentrated atmosphere adjacent to the gas inlets; second, to provide some slight movement of gas in the furnace; third and most important, to make it possible to feed gas to the furnace in sufficient volume to maintain a positive pressure at all points, while at the same time avoiding the necessity of adding too much hydrocarbon. In all continuous furnaces sufficient gas to flush the furnace vestibules adequately is mandatory, and is usually more than sufficient to maintain positive furnace pressure.

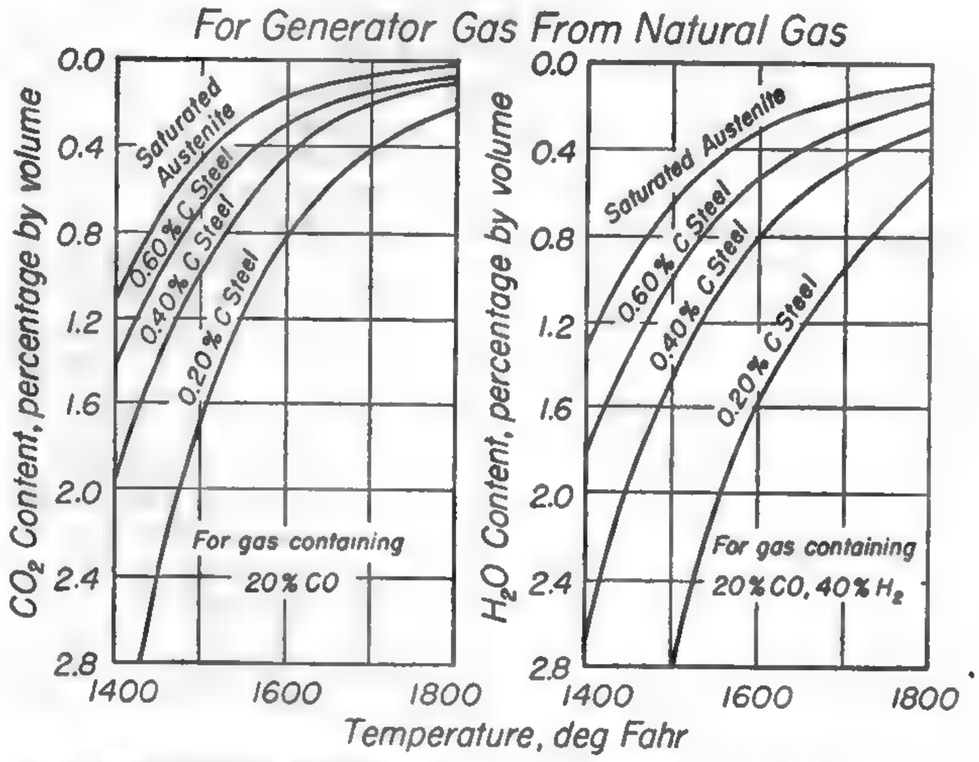

Fig. 1 Equilibrium curves for generator gas from natural gas

A good diluting gas must be neutral or only slightly carburizing in its action with high-carbon steel at the temperature of carburizing.

Decarburizing Diluents. The diluting gases first used in gas carburizing were air or slight variations from the gases now used for bright annealing low-carbon steel. All of them were actively decarburizing and required an excessive hydrocarbon addition to accelerate the intergaseous reactions by which the decarburizing agents were eliminated. This excessive hydrocarbon addition, in turn, caused soot to be deposited on the parts being treated. However, any reduction in hydrocarbon to avoid the deposition of soot often resulted in nonuniform carburizing, since the decarburizing agents were permitted to persist too long. No furnace should be operated with a diluting gas of this type.

Charcoal Gas. The first nondecarburizing diluting gas employed commercially was charcoal gas[4] made by passing air, or products of partial or complete combustion of a fuel gas, through a retort containing charcoal maintained at 1700 F or above. Here, by reaction with the charcoal, the gas mixture loses its decarburizing tendency and becomes mildly carburizing in its action.

Catalytic Gas Generators. The charcoal gas generator has now been replaced largely by one that produces an equivalent and very similar product, through the use of a catalyst, to accelerate the reactions shown below. An accurately controlled mixture of air and natural gas, or air and propane, first burns above the catalyst to form considerable carbon dioxide and water vapor, leaving an excess of hydrocarbon unchanged. This hydrocarbon then reacts on the heated catalyst with the carbon dioxide and water vapor, by the chemical equations below:

$$CH_4 + CO_2 \rightarrow 2CO + 2H_2$$
$$CH_4 + H_2O \rightarrow CO + 3H_2$$

In a well-designed unit little or no hydrocarbon in excess of that required by these reactions need be used, and the reactions proceed to the right to virtual completion.

This type of gas generator, first described by J. R. Gier,[5] has several advantages over the charcoal unit—chiefly the lower cost of maintenance, since there is no charcoal or ash to handle.

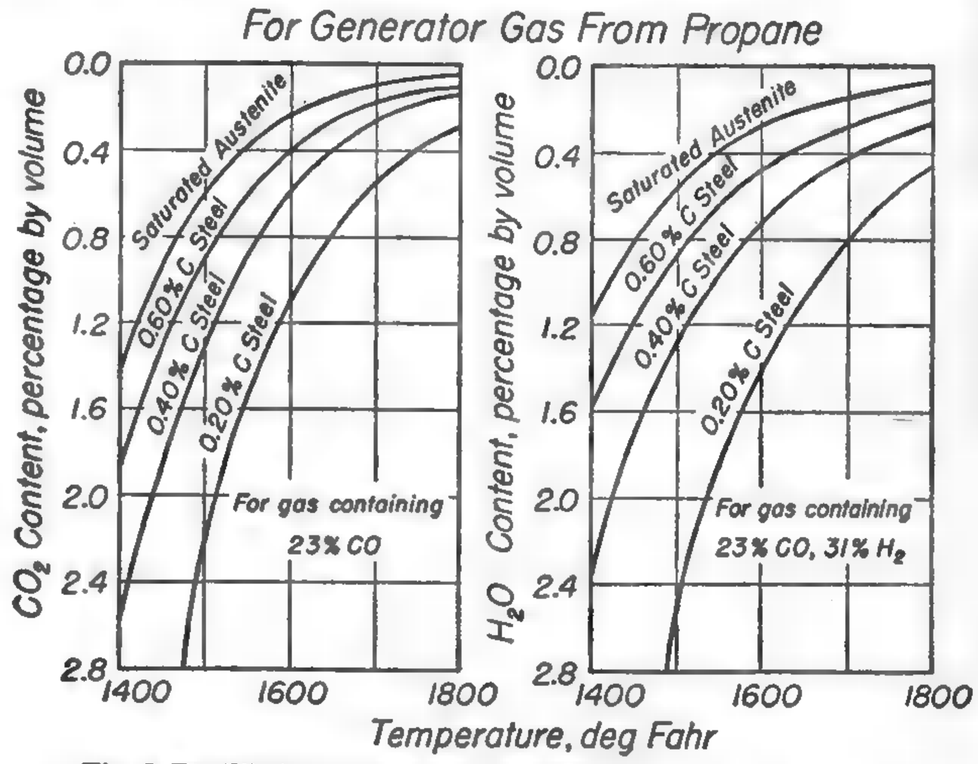

Fig. 2 Equilibrium curves for generator gas from propane

The following observations may be of value in the successful operation of one of these units:

1 For best results, the ratio of gas to air must be held within plus or minus 1% of the desired ratio. Any excess of gas causes formation of soot on the catalyst and this should be avoided as far as possible.
2 The activity of the catalyst decreases as soot accumulates on it.
3 The activity of a nickel catalyst is destroyed by gases containing sulfur.
4 Finely divided nickel deposited on a carrier is more active than an apparently equivalent surface of fused nickel or reduced nickel scale.
5 Finely divided nickel is much less active if overheated, a condition very difficult to avoid when burning out the generator, if any great amount of soot is allowed to accumulate.

The catalytic gas generator is also used widely for clean hardening, and since the requirements of a gas for clean hardening are closely related to those of a diluting gas for carburizing, the curves in Fig. 1 and 2 will be of value for both. These curves show at a glance the composition of gases prepared catalytically from natural gas and from propane, in equilibrium with any steel, at any normal operating temperature. For example, if it is desired to harden 0.40% C steel bolts at 1550 F, avoiding both carburizing and decarburizing, the composition of an atmosphere prepared from natural gas is obtained from Fig. 1. The 1550 F line intersects the 0.40% C curve at a point opposite 0.7% CO_2 on the ordinate of the curves for CO_2, and 1.1% water vapor (dew point, plus 48 F) on the water vapor curves.

Such an atmosphere can be made and controlled by varying the amount of air that is added to a constant volume of generator gas of the catalytic type. The addition of air should be regulated to keep the composition of the furnace atmosphere constant at these values.

Restoration of Carbon Content. In a like manner, decarburized parts may be returned to their original content

of surface carbon within commercial limits, by varying an addition of hydrocarbon or air (depending on the degree of decarburization) to a generator gas of the catalytic type, to maintain the CO_2 and H_2O contents of the furnace atmosphere at the values dictated by the original carbon content of the steel, and by the operating temperature. Figures 1 and 2 are useful here also. The time required at temperature to meet most commercial requirements is the time required to produce a case equal in depth to the total depth of any apparent decarburization. For uniformity of product, as well as for ease in obtaining representative samples of gas, circulating fans are advisable in this type of work and are mandatory for such parts as bolts loaded several layers deep.

Other Diluents. Diluting gases constitute a large percentage of the products of initial pyrolysis of certain liquid hydrocarbons that contain oxygen, and some dilution is brought about in this way in furnace atmospheres prepared from oil.[6] In general, the degree of dilution obtainable is less than is desirable, particularly in furnaces that have been used for some time, since all furnaces are likely to develop small leaks with use.

Coke-oven gas with several times its volume of spent carburizing gas drawn from the furnace chamber has been used successfully as a diluting medium for propane and for natural gas. A similar treatment of the water-gas type of manufactured gas has not proved successful.

Furnace Operation. Many of the requirements for successful control of a gas carburizing furnace can be deduced from the previous discussion and can be listed as follows:

1 Volume of Gas. Gas must be fed to the furnace in sufficient volume to flush any furnace vestibules adequately and to maintain a positive pressure at all points in the carburizing chamber. A furnace can be considered a low but very effective chimney. Infiltration of air tends to occur at the bottom of the chamber or around fan shafts where there is usually a low-pressure area resulting from the action of the fan.

This requirement normally dictates the use of a diluting gas that must be of proper and constant composition. Good practice calls for generous quantities, preferably constant in volume.

2 Regulation of the Hydrocarbon Addition. Carburization is controlled by regulating the hydrocarbon addition.

In the operation of batch furnaces, this addition should be reduced periodically (usually once or twice) as the carburizing cycle proceeds, more or less in accordance with the demand of the steel for carbon. The hydrocarbon addition is normally somewhat greater than that required for producing and maintaining a surface layer of saturated austenite. If cases lower in carbon are desired, a carburizing period can be followed by a diffusion period; that is, a period during which diluting gas only is fed to the furnace, allowing some of the carbon at the surface of the steel to diffuse inward. A reduction in the carbon content of the surface and an increase in depth take place.[7]

A recent article by Harris[8] presents a method of calculating the length of carburizing and diffusion periods to produce various gradients of carbon content.

In continuous furnaces the hydrocarbon addition is varied to maintain a constant methane content in the furnace atmosphere, but if the methane content is to be an adequate measure of the carburizing activity in a given furnace, the following must be held constant:

(*a*) Composition of the hydrocarbon supply.
(*b*) Composition and volume of the diluting gas. With a varying methane content in the diluting gas, the methane content of the furnace atmosphere cannot be a measure of its ethane or propane content and has been reported as a cause for poor control of the carburizing. (*See* Methane Content, page 689.)
(*c*) Proportioning the hydrocarbon supply to the various inlets.
(*d*) Adequate furnace pressure and flushing of the vestibule. Any infiltration of air can seriously upset the carburizing balance.
(*e*) Any uncontrolled addition of hydrocarbon (for instance, quenching oil fumes) must be avoided.

To produce cases with the surface carbon content below saturation in a continuous furnace, it is necessary merely to reduce the hydrocarbon content of the furnace atmosphere by reducing the volume of the hydrocarbon added. Unless proper precautions are taken, however, this may give an atmosphere too weak in hydrocarbon in the first carburizing zones, causing the formation of very low-carbon cases in the first few hours of the cycle. Then as the parts progress through the furnace, the surface carbon content and the case depth both increase, resulting in a much shallower depth of hardenable case than would otherwise be obtained in a given time. This phenomenon is most noticeable when the carburizing time is short—for example, less than four hours. From previous discussion, to avoid this it is necessary to have several times as great a concentration of hydrocarbon during approximately the first half hour of carburizing as in the last zone. (*See* observation 5 above.)

It is worth mentioning here that the method of carbon control described for recovering carbon at 1500 to 1550 F cannot be used successfully at 1700 F. Reference to the curves of Fig. 1 and 2 shows that methods of analyzing gas for carbon dioxide and water vapor are not accurate enough for control. But even if more accurate methods of analysis are developed, the speed of the reactions between these gases and hydrocarbons at 1700 F is too great for representative samples to be obtained.

3 Furnace Conditioning. A varying degree of furnace conditioning must either be prevented or compensated for. Most furnace alloys can be carburized and decarburized almost as extensively as steel, and the depth to which the alloy is carburized can affect considerably the rate of demand for carbon. Since the furnace alloy usually has a large surface area, considerably more hydrocarbon must be fed to a new furnace, or to an old one that has been left open at temperature for any long period, than to one that has been thoroughly conditioned. The furnace brickwork may also contribute to this phenomenon.

It is good practice to keep batch furnaces closed tightly whenever they are not in use, and to allow them to cool if the idle period is to be an hour or more. To test for the furnace condition, determinations of dew point or CO_2 can be made on the effluent gas from an empty furnace at temperature, while diluting gas only, or diluting gas with about 10% of the normal addition of hydrocarbon is being fed to the furnace. At 1700 F, the CO_2 content should not exceed 0.2% and the dew point should not exceed plus 10 F, if catalytic generator gas is the diluting medium.

Continuous furnaces require periodic burn-outs, which should be as rapid as the accompanying increase in furnace temperature will permit. The furnace should then be closed immediately and kept closed until it is to be prepared for operation. During this holding period, residual carbon in the furnace serves to recarburize the alloy partially. In preparation for carburizing, generator gas plus approximately 20% of the normal hydrocarbon addition should be fed to the furnace, until the dew point of the furnace atmosphere drops to plus 5 F or lower. Operation can then be started and the hydrocarbon addition can be increased to obtain the desired methane content in the furnace atmosphere. The volume of hydrocarbon addition required to maintain a desired hydrocarbon concentration usually decreases gradually for 48 hours or more, and then becomes fairly constant for a long period.

It is general practice to burn out continuous furnaces during week ends if required. On other week ends, the emptying of the furnace of stock may be avoided in many instances by shutting off the hydrocarbon addition and cutting the furnace control temperature to approximately 1350 F. Often this treatment reduces the carburizing rate to such an extent that the parts are not carburized beyond acceptance.

Comments. No attempt has been made to describe the many types of gas carburizing furnaces now being produced. The reader is referred to the furnace manufacturers.

The following additional observations may be of interest:

1 The life of cast heat-resistant alloy in carburizing atmospheres is apparently governed more by the soundness of the casting than by any other factor.

2 Rolled alloy is normally not subject to serious gas attack but may carburize. Rolled alloy is serviceable much longer than cast alloy, provided the structure is not subject to failure in welds.

3 The rate at which gas will attack furnace alloy is a

function of the penetrating power of the gas. (*See* observation 6 above.)

4 Oil fumes can be very objectionable in a continuous furnace because they contain sulfur; furthermore they tend to overcarburize protruding surfaces and to disturb the hydrocarbon balance otherwise.

5 It should be recognized that the gas carburizing process is still in a state where developments are coming in rapid succession, accelerated by the demand of metallurgists for cases that have the carbon content of the surface controlled within definite limits. Better methods of case control will probably be developed. Better instrumentation should play a large part in the progress of gas carburizing.

Liquid Carburizing

By Robert J. Peters*

LIQUID CARBURIZING is a method of case hardening or carburizing steel or iron in a molten salt bath that contains the chemicals required to produce a case comparable with one resulting from pack or gas carburizing. Carburizing in liquid baths provides a convenient method of case hardening, with low distortion and with considerable flexibility and uniformity of control of the case.

Liquid carburizing may be distinguished from cyaniding by the character and composition of the case. The cyanide case is high in nitrogen and low in carbon. The reverse is true of liquid carburized cases. The rate of penetration of carbon in liquid carburizing is faster than that in cyaniding, at a given temperature. Cyanide cases are seldom applied more than 0.010 in. deep, but carburizing baths permit cases as deep as 0.250 in. For very thin cases, light-case carburizing baths may also be used instead of straight cyanide.

Chemistry of Liquid Carburizing. The carburizing action depends primarily on the sodium cyanide, activated or catalyzed by the presence of alkaline earth salts—usually barium, calcium or strontium salts. The formation of sodium cyanate is greatly reduced and less nitrogen and more carbon are liberated. The basic reaction may be represented by the equation:*

$$Ba(CN)_2 + 3\,Fe \rightarrow Fe_3C + BaCN_2$$

Barium cyanide + Iron → Iron carbide + Barium cyanamide

The carbon liberated by the shift from barium cyanide to barium cyanamide, is absorbed by the steel and the small amount of nitrogen available is absorbed, producing a beneficial effect on the file hardness of the surface.

Table I. Compositions of Liquid Carburizing Baths[a]

Salt	Composition, percentage — Light-Case Bath	Deep-Case Bath
Sodium cyanide	17 to 23	7½ to 12
Barium chloride	15 to 40	45 to 55
Other alkaline earths	0 to 3½	2 to 10
Potassium chloride	.....	5½ to 20
Sodium chloride	20 to 30	0 to 15
Sodium carbonate	30 max	30 max
Sodium cyanate	1 max	0.30 max

(a) R. S. Komarnitsky, Metal Progress, 50, 665 (Oct 1946)

For general use, the most economical operating range of liquid carburizing baths is 1550 to 1750 F. Higher temperatures may be used, providing faster penetration, but at increased material cost and deterioration of equipment.

Light-case baths, operating from 1550 to 1650 F and having an average cyanide content of 20%, produce cases as deep as 0.030 in. Deep-case baths average 10% cyanide and operate at temperatures of 1650 F and higher.

Composition of Bath. Compositions of light-case and deep-case baths are given in Table I.

* Chief Metallurgist, Warner Gear Division, Borg-Warner Corporation, Muncie, Ind. Prepared for the Subcommittee on Carburizing

* Barium cyanide is formed by reaction between sodium cyanide and barium chloride in the bath.

Although most of the carburizing baths use sodium cyanide as the active element, a proprietary bath utilizing calcium cyanide has been employed successfully, particularly for case depths up to 0.035 in. The calcium cyanide content of such a bath is approximately 0.5%. The most serious disadvantage of the calcium cyanide type of bath is the necessity for using approximately 70% of calcium chloride, a highly hygroscopic salt, which makes necessary special precautions to avoid rusting of the finished work.

Temperature and Duration of Carburizing. Carburizing baths operating at less than 1650 F produce case characteristics similar to those that result from cyanide, as the temperature approaches 1500 F. Nitrogen content increases and the carbon content decreases. At 1650 F and higher, the carbon content and metallographic characteristics of the case are similar to those from gas or pack carburizing.

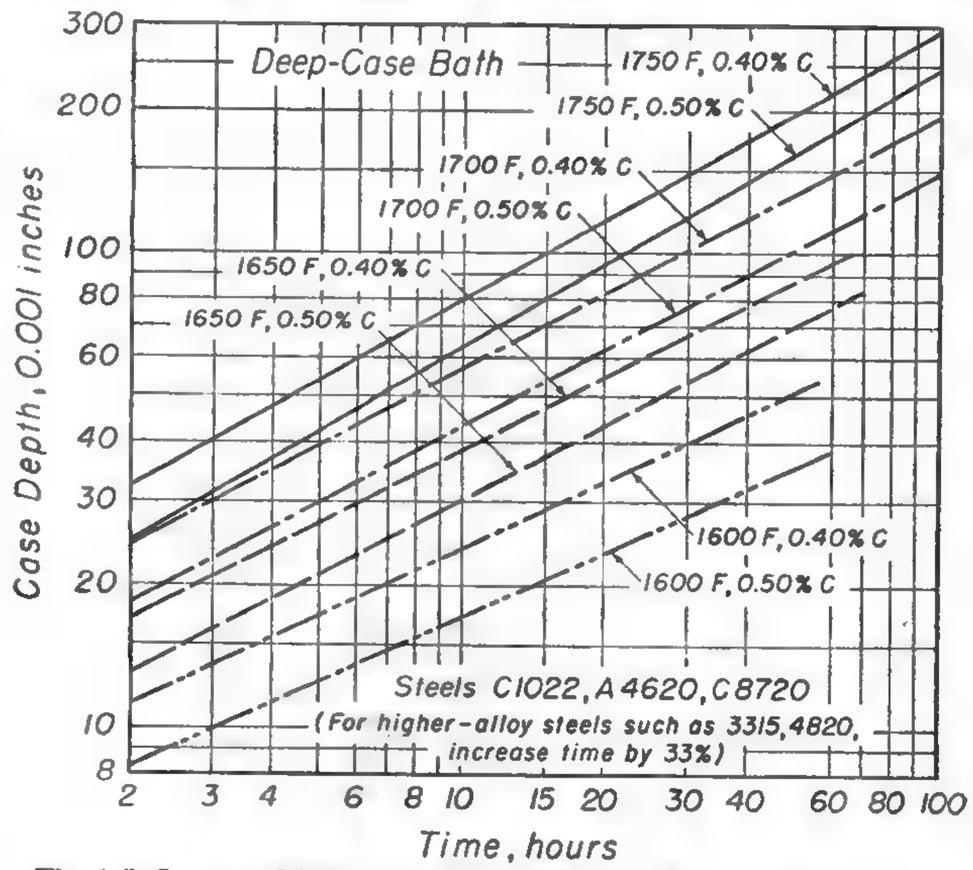

Fig. 1 Influence of time and temperature on the case depth of steels C1022, A4620 and C8720, carburized in deep-case bath (R. S. Komarnitsky, Metal Progress, 50, 665, Oct 1946)

Time-penetration values for various steels processed in light-case and heavy-case baths, are shown in Fig. 1 and 2.

Process. The mechanism of carburization in the salt bath is quite similar to that in other carburizing mediums. Sodium cyanide or barium cyanide supplies carbon and in the process some nitrogen is liberated. The article on "Mechanism of Carburization" in this Handbook (page 678) discusses the technical data and describes diffusion phenomena characteristic of all standard carburizing mediums, including those used in liquid carburizing.

Two types of mixtures are available for carburizing baths: one type contains all the ingredients in the proper balance to maintain continuous action; the other requires the mixture of a neutral base and activated cyanide.

Periodic addition of catalytic material keeps the bath in operating condition. The single bath is more expensive to maintain since drag-out replacement is usually insufficient to maintain the proper composition. Frequent ladling is therefore necessary to allow for make-up additions. The baths may be adequately controlled by analysis for cyanide and frequent checking of case depth.

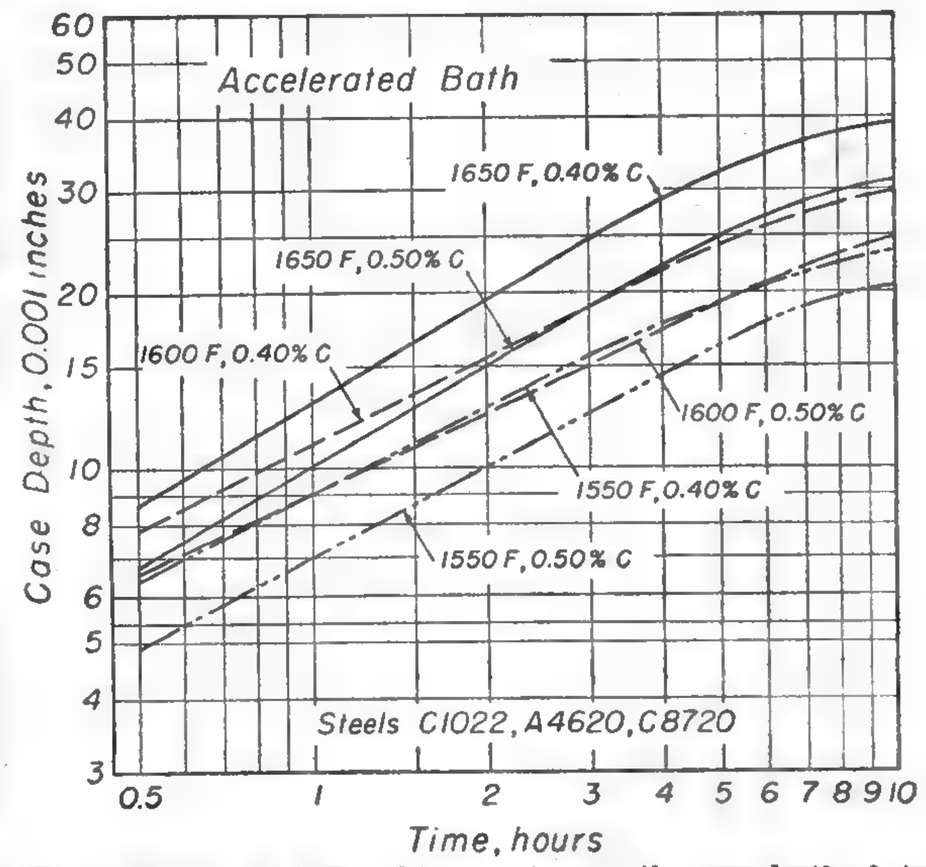

Fig. 2 Influence of time and temperature on the case depth of steels C1022, A4620 and C8720, carburized in accelerated (light-case) bath (R. S. Komarnitsky, Metal Progress, 50, 665, Oct 1946)

Liquid carburizing baths should have a "cover". This cover is ordinarily incorporated into the salts but may be produced or maintained by the addition of low-silica graphite to the molten bath.

Precautions. The precautions necessary for handling liquid carburizing salts are the same as for any cyanide mixture. Work material must be clean and dry and the bath must be enclosed and well ventilated. The raw material and baths contain cyanide but, when handled properly, this chemical should not present a serious hazard to health or safety.

Parts treated with accelerated salts and quenched in oil, may be cleaned in spray washers with clear water. Cleaning compounds often render deposits very hard to remove. Any white deposit remaining on a work piece may be removed by immersion in 2% hydrochloric acid, followed by a dip into an alkaline solution of 2 or 3 oz of soda ash per gallon.

Equipment. Two general types of equipment are available for external and internal heating. Baths operating at temperatures lower than 1650 F may be heated externally with gas, oil or electricity. Above 1650 F, internal electrode heating is almost imperative.

Cast steel pots give excellent results when properly installed and cared for. Heat-resisting alloy pots give proportionately greater service for low-temperature baths. High-temperature baths require alloy cast or welded plate containers. Ceramic containers with built-in electrodes are successful for liquid carburizing baths.

Specially designed pots and furnaces may also be adapted to operations in continuous sequence. Heat treating in liquid carburizing baths may be almost completely mechanized with consequent improvement in economy, uniform treatment of work in process and adaptability to continuous production.

Selective Carburizing

By L. A. Lanning* and R. W. Woodward*

SELECTIVE carburization is used when certain portions of the surface are to remain soft after hardening, in order to permit machining, polishing and straightening, to increase toughness and to control distortion.

Selective carburization may be obtained in many ways, but only the principal methods will be considered here. In practice, it is more difficult to obtain selective carburizing with gas carburizing than with pack carburizing.

Excess Stock at the Surface Portion Desired Soft. Excess stock is left at portions desired soft. After the carburizing operation, the piece is cooled slowly. The excess stock is then machined off to below the case so that the piece will have a soft surface area after the hardening treatment. For certain types of tool work or where few pieces are to be treated, this is an excellent method. Where threads or sharp corners are to be left soft, this method is perhaps the most reliable.

Sand Packing. The work is packed in sand so that only the desired portions are exposed to the carburizing compound. The line between the hard and soft portions will not be sharp, since the gas from the compound penetrates the sand to a slight depth. This method cannot be used with compounds that have a high shrinkage, because the sand will be displaced, causing hard spots at the protected points. The sand should be fairly fine, and reasonably free from dirt. It must also be thoroughly dried before packing; otherwise caking will occur, exposing surfaces that should be protected. It is an advantage to have the sand at the bottom of the carburizing container and to subject the container to as little jarring as possible after the pieces have been placed in it.

Covering Parts Desired Soft with Cement. For preventing carburization of tapped holes and bores of gears, a satisfactory method is to plug these parts with a cement made of finely sifted fire clay mixed with sodium silicate (water glass). The proportions (approximately 2 parts fire clay, 1 part sodium silicate, and 1/10 part water) should be regulated to secure a cement that will not crack or shrink excessively during heating and firing. The addition of sand to the cement will sometimes help to prevent shrinkage. After carburization the cement may be knocked out of the holes. Although this cement will form glass, it is possible to apply it carefully to external surfaces; but it is less satisfactory than other covering materials. Prepared cements are available.

Such parts as bushings, sleeves and piston pins are often strung on close-fitting steel rods, a practice that minimizes the case in the bore.

Covering Parts Desired Hard with a Carbonaceous Cement. Selective carburization is obtained by covering the portions to be carburized with a carbonaceous paste or cement, which acts as the carburizing compound. After the work pieces have reached the proper temperature, the portions covered with the paste are carburized and the other portions are unaffected. With this method, the case will not be sharp, but will gradually slope to the portion of the work desired soft.

Protection with Copper Forms. Copper, in the form of tubing, bars, cups, sleeves and disks, is used to prevent carburization of tapped holes, piston pins and ends of shafts. The copper form is placed on or in the work with a clearance of not more than 1/64 in. This method is not completely efficient but substantially decreases both the depth and the carbon content of the case.

Solutions or Pastes. Solutions or pastes are now available that are quite effective in preventing the carburization of surfaces to which they are applied.

Electrodeposited Copper. Electrolytic methods of copper plating are the most widely used where production warrants the expense of installation and operation. Copper plating is effective with most carburizing compounds, although with certain compounds copper does not prevent carbon from penetrating. Besides there is considerable

* Plant Manager, New Departure Division, General Motors Corporation, Sandusky, Ohio
* Engineer of Tests, Underwood Corporation, Hartford, Conn.

difficulty in depositing the copper plate in recesses. Two methods may be employed when using copper plate:

Plating the Entire Piece. The entire piece is plated and then the copper is removed by machining or grinding from the portion which is to be hardened.

Selective Plating. By the use of suitable protective paints, copper plating can be applied so that the areas where hardness is desired remain free from copper. In the usual method a baking japan or suitable lacquer is painted on the area to be hardened and is then baked or dried. Then the plating may be performed in the usual manner, but no plate will form on the *covered* surfaces. In the carburizing operation the japan or lacquer burns off, permitting the carburizing gases to penetrate the areas that are desired hard. Masking may also be done with rubber or with wax stop-off.

The copper-plating operation is standard. The chief requirement is to produce a fine-grained, continuous plate. For compositions of plating baths, see page 718.

Precautions. Certain precautions must be observed for successful plating and selective carburizing.

1 The parts must be thoroughly cleaned before painting, and the japan or lacquer must adhere tightly.
2 Before the plating operation, the work must be chemically clean. Usually the pieces are first dipped into a metal cleaning solution, and are then washed in water, dipped into weak hydrochloric acid, washed in water, dipped into a cyanide solution and again washed. This procedure may seem elaborate, but it is necessary if complete protection is to be assured.
3 Care must also be taken to insure that the bath is of the proper concentration to give a solid continuous plate.
4 The thickness of copper plate necessary for protection depends on a number of factors, such as the plating method used, the duration of carburizing and the carburizing temperatures. However, for satisfactory protection in most carburizing work, a minimum plate of 0.0003 in. should be maintained.
5 Copper plating should not be subjected to oxidizing conditions before or during the carburizing operation, because the protection afforded by the plating will be destroyed.

The above methods for selective carburizing are successful under certain conditions, but their use depends largely on plant conditions and the type of work.

Cyaniding

By H. B. Northrup*

A HARD, superficial wearing surface or case can be obtained rapidly and satisfactorily on low-carbon steels by means of the cyaniding or case-hardening process. Steels treated by this method absorb both carbon and nitrogen from the molten salts; then when quenched in water or a suitable oil, they develop appreciable hardness in the case.

Because of greater efficiency and lower cost, sodium cyanide is now widely used instead of the more expensive potassium cyanide. For case hardening, sodium cyanide is used in either of two ways: (1) as a powdered mixture into which the red hot steel is dipped or which is applied to the heated surface of the steel; or (2) as a molten bath in which the steel to be treated is immersed long enough for the reactions to take place.

Caution. Cyanides are violent poisons if allowed to come in contact with scratches or wounds—for example, on the hands; they are fatally poisonous if taken internally. Also fatally poisonous fumes are evolved when cyanides are brought into contact with acids.

Properties of Sodium Cyanide. In the case hardening of steel, sodium cyanide is used in four different strengths or grades. Each of these grades, because of its chemical composition, has individual properties as shown in Table I.

Molten sodium cyanide is decomposed quite rapidly when heated above 1580 F in an open pot. The heavy white fumes that arise from the bath are not especially dangerous, although they are decidedly obnoxious because they irritate the mucous membrane in the nasal passage and thereby induce violent sneezing. When these fumes are disseminated in the air, they become almost entirely sodium carbonate, neither dangerous nor particularly detrimental to health or property, but annoying. The escape of the fumes can be prevented by the installation of equipment for gathering and washing fumes. The equipment includes a suction fan, which draws the fumes from the pots and passes them through a large washing drum and water spray (mist) before they are vented into the outside air. The washers and the spray dissolve the sodium carbonate fume and precipitate any solids carried by the ventilating apparatus.

The chemistry of the decomposition of the bath involves the oxidation of the sodium cyanide to sodium cyanate by the application of heat and exposure to oxygen in the air as follows:

$$2NaCN + O_2 = 2NaCNO$$

It is probable that, in order to carburize steel, the sodium cyanate (NaCNO) in the bath must exceed a definite minimum concentration and must be kept uniform by means of regular additions of sodium cyanide. Baths high in cyanide but free from cyanate have no carburizing action. Fortunately this condition is very rare, since the formation of cyanate is automatic, according to the reaction above. Continued heating of sodium cyanate in air forms sodium carbonate, carbon dioxide and nitrogen, as follows:

$$4NaCNO + 3O_2 = 2Na_2CO_3 + 2CO_2 + 2N_2$$

Sodium cyanide is a strong reducing agent in the molten state, readily reducing the oxides of most metals. It is deliquescent and gradually decomposes if left in an open container, because of the action of moisture and carbon dioxide. Sodium cyanide is soluble in water and the solubility of the anhydrous salt is almost independent of the temperature.

Uses of Sodium Cyanide. *96 to 98% Sodium Cyanide.* In the heat treatment of steel, powdered sodium cyanide (96 to 98% NaCN) is sprinkled on red hot steel, for case hardening; as a "sweetener" to replenish the cyanide content of depleted baths for case carburizing; as a bath material for carburizing directly with cyanide; and in admixture with potassium cyanide for nitriding steel by immersion in a bath.

75% Sodium Cyanide. This mixture is sometimes used as a bath for direct carburizing with cyanide, but because of the volatility of the cyanogen (CN) radical, the use of 75% NaCN in heavy production work is not recommended. More frequently 75% NaCN is used as a replenishing material to raise the cyanide content of depleted baths or to maintain concentrations by regular additions.

45% Sodium Cyanide. This mixture is recommended as a suitable bath for the general case carburizing of low-

carbon and alloy steels. It is very fluid at the operating temperature. The addition of "inerts" (sodium chloride and sodium carbonate) to sodium cyanide tends to retard the decomposition of the sodium cyanide without being detrimental to the case carburizing properties. When this mixture is used continuously in production work, the strength of cyanide will need to be maintained nearly constant by addition of the 96 to 98% or the 75% NaCN.

30% Sodium Cyanide. When the case carburization of low-carbon and alloy steels is to be maintained under conditions of heavy production, 30% NaCN is preferable to any of the preceding mixtures. It has the lowest first cost and, because of the content of inert material, the decomposition of the sodium cyanide of the bath is greatly retarded without detriment to the case carburizing properties.

It is necessary to keep the strength of the bath constant by addition of either the 96 to 98% or the 75% NaCN. The 96 to 98% NaCN is preferable because of the absence of inerts in material of that concentration. The bath is already loaded with sufficient inerts to "fix" the concentrated material, which should be added in proper amounts at regular intervals. If the cyanogen content of the bath is too low, the bath tends to decarburize and cause scaling of the work material. "Drag-out" of the bath material is replenished by the 30% NaCN as needed.

The Cyanide Bath. Baths of sodium cyanide are employed as a heating or reheating medium in connection with the hardening of steels, or to prevent surface decarburization, thus producing work with a clean surface; and to act as a liquid medium for case carburizing, affording a quick, efficient and economical means of obtaining a hard superficial wearing surface. Baths to accomplish the first purpose are discussed on page 283. To accomplish the second purpose (that is, to act as a liquid medium for case carburizing) a bath regulated to maintain a uniform 30% NaCN concentration has been found to meet all the requirements.

When low-carbon and alloy steels are to be cyanided to produce a good wearing surface, the surface must usually be backed up by a fine-grained, tough core. This requires an operating temperature of approximately 1600 F in the bath. Case depths and carbon concentrations for three steels are given in Table II. These results show the inefficiency of cyanide as a medium for obtaining deep penetration of carbon. They also show that even after a 1-hr immersion, the carbon concentration is insufficient to account for the extreme hardness obtained from quenching cyanided steels. Usually immersions range from 30 min to 1 hr and produce case depths and carbon concentrations corresponding to those given in the table. Lowering the temperature will correspondingly and proportionately lower the results given in the table.

Since the results obtained in the practice of cyaniding steel are directly proportional to the four variables—time, temperature, mass, and cyanide concentration of the bath —the data in Tables III, IV and V, all derived from the heat treatment of SAE 1020 steel, show clearly the results of accepted practice involving these variables.

Within the range of time used in commercial cyaniding practice, almost the same depth of case is produced in steels of different compositions. The nickel and nickel-chromium steels give a nicer carbon gradient from case to core than do the carbon steels, but at the same time exhibit a lower concentration of carbon in the case.

The hardening properties imparted to the steel by the added carbon are not entirely responsible for the file hardness obtained after cyanided steel has been quenched in water. One of the decomposition products of a sodium cyanide bath is nascent nitrogen, and evidently some of this nitrogen combines with the iron of the steel, forming the extremely hard and brittle iron nitride.

Cases obtained by the cyanide process are hard and resist wear, although they do not contain the high concentration of carbon possible with solid carburizing compounds.

Generally, the steels that are case carburized by packing in solid carburizing material, or that are subjected to a carburizing gas, can also be carburized by cyaniding. They are usually treated by the liquid bath method because of some particular advantage of the process, such as speed of production, the economies of the process, or the peculiar quality of hardness desired in the resultant case.

Ordinarily, cyaniding should be carried out at a temperature just higher than the upper transformation point of the core, and the steel should be quenched directly from the cyaniding temperature. At this temperature the case, which does not approach a tool steel composition and which has not been held for a sufficient length of time to cause brittleness from excessive grain growth, will quench to the desired hardness, and the core will be thoroughly refined and tough.

Control of Temperature. Liquid carburizing and nitriding operations are usually performed under standardized conditions; namely, a standard weight of pot, a standard weight of salt per pot, a standard weight of steel treated for a standard length of time at a predetermined temperature, for any given set of physical requirements. Under these conditions, the "time to come to temperature" and the "time at temperature" can be standardized by controlling the temperature of the heating chamber.

"Nitriding" in a Molten Salt Bath. Molten cyanide salts have been widely adopted as an agent for increasing the surface hardness of high speed steel tools by building up the nitrogen content of the case. (*See* page 283.)

Quenching of Cyanided Steels. Whether to quench in oil or water depends on the requirements of the service for which the cyanided steels are intended and on the chemical composition of the steel. When water is used, it should be as free as possible from dissolved gases, which have a tendency to produce soft spots; so for straight hardness quenching, water should not be agitated by means of air. For maximum hardness and to minimize warpage, the water should be moving, except where long or thin cyanided parts are to be quenched, and normally it should be as cold as possible.

For oil quenching, a mineral oil should be used. The blended mineral-animal hydrocarbon oils should never be used for quenching cyanided steel, because the fatty matter of the animal oil will saponify with the decomposition product of the cyanide bath (alkali), causing the formation of a hard soap. This soap will retard the quenching speed of the oil and may also clog the drains.

Hardness of Cyanided Steels. The usual requirement for the hardness of cyanided steel for shop production is "file hard". This value of hardness is subject to many

ramifications, but it is still the criterion for testing hardness in the shop. The Rockwell C impression and the scleroscope are also used for testing cyanided surfaces.

The depth of the cyanided zone is determined best by means of the microscope. The cyanided case is composed of two fields distinct in character—a martensitic outer zone and a troostitic inner zone of lower carbon content. The case depth is usually determined by measuring the distance from the outer edge of the specimen to the center of the second zone.

In steels that are cyanided and that do not contain more than 0.65% C in the case, the hardness cannot be attributed to the carbon content alone. Since one of the decomposition products of the cyanide bath is nitrogen, iron nitride, an extremely hard and brittle product, is formed. At the lower cyaniding temperatures (about 1425 F) a considerable amount of iron nitride is observed in the form of nitride needles and patches. When the temperatures are approximately 1550 F, few of the nitrides are observed, but it is generally accepted that this iron nitride in indistinguishable form produces the hardness otherwise unattainable from the additions of carbon.

Although the absorption of nitrogen affects the hardness of the case, by the formation of iron nitrides, the core is not affected. Steel of the proper grade, which has been cyanided above the transformation range of the core and quenched into water, will snap readily when subjected to stress. When the case is removed by grinding, the core is found to possess ductility. The apparent brittleness may result largely from a notch effect in the core after a crack has been formed in the hard case.

Cyanide Containers. Many types and compositions of cyanide containers have been used to hold the molten salts. Most of them are cylindrical with hemispherical bottoms; if the containers are rectangular, the corners are well rounded. They are constructed of gray cast iron, cast steel, pressed steel and cast nickel-chromium alloy, with the cost and the life both increasing in about the same order. This subject is discussed more fully in an article entitled "Salt Baths", on page 283 of this Handbook.

Carbonitriding (Gas Cyaniding)

By J. A. Dow*

CARBONITRIDING, known also as "gas cyaniding", "dry cyaniding", and "ni-carbing", is a process for case hardening a steel part in a gas carburizing atmosphere that contains ammonia gas in controlled percentages. Both carbon and nitrogen are added to the steel; the nitrogen serves chiefly to reduce the critical cooling rate of the case. The carbon content of the surface of the case is controlled as described in the article entitled "Gas Carburizing", on page 688. The nitrogen content of the surface is controlled by maintaining the desired ammonia content in the furnace atmosphere, through varying the amount of the ammonia additions.

When the work pieces are to be quenched, the ammonia content of the atmosphere need not exceed 1%, except for special surface requirements, and may be as low as 0.1%. For work that is to be cooled in an air blast, the ammonia content in the furnace atmosphere is usually between 1 and 5%. When the case is to be formed at 1300 to 1400 F and the steel is to be cooled slowly, the atmosphere may contain as much as 15% ammonia.

The nitrogen and carbon contents of a steel part after carbonitriding at a given temperature, decrease from the surface to the core, and since both nitrogen and carbon contents have a pronounced effect on the critical cooling rate, the depth of case must always be considered in terms of the depth of effective or hard case. Carbonitriding is no different in this respect from other methods for producing carbon-nitrogen cases—for instance, cyaniding.

Carbonitriding is normally carried on above the Ac_1 temperature of the steel and the process is practicable up to 1700 F. The depth to which carbon and nitrogen penetrate the metal, varies with temperature and time. The rate of penetration of carbon is apparently quite close to that obtained in carburizing (*see* page 678).

By far the widest application for carbonitriding is as a low-cost substitute for cyaniding. The operating costs may be as low as one-fourth the cost of cyaniding in modern electrically heated baths. Since both the carbon and nitrogen contents of the case can be controlled, the rate of cooling attained in an oil quench is as rapid as is ever required for file hardness of the surface. As in other methods of heat treatment, oil quenching has a marked advantage over water quenching, where distortion is concerned. The martempering form of quenching after carbonitriding, has reduced distortion still further on certain parts, and seems likely to become increasingly popular in the future.

Very small additions of ammonia to a gas carburizing atmosphere are sufficient to impart, to any of the standard carbon or low-alloy steels, sufficient hardenability for the attainment of maximum surface hardness with an oil quench. Frequently the immediate subsurface portion of the case is largely austenitic when the concentrations of ammonia used are high enough to give full hardening in oil to the low-carbon hypoeutectoid portion of the case. But in contrast with the low wear resistance that might normally be expected, such cases have been reported to wear many times longer than the best carburized or cyanided cases previously produced. After careful metallographic preparation, microscopic examination usually reveals a very thin layer of some constituent other than austenite or martensite on the immediate surface of a carbonitrided specimen, and the surface is file hard.

From the standpoint of operating cost, any method of carbonitriding without quenching should not be considered until the methods that involve quenching have been proved unsatisfactory because of excessive distortion. To reduce the critical cooling rate of a carbonitrided case sufficiently for it to have satisfactory hardness after quenching in an air blast, the ammonia addition must be increased so greatly that the operating cost is often doubled and in some instances trebled. However, these relatively high costs may be lower than the cost of liquid cyaniding. The file-hard surface constituent mentioned above has been formed successfully with gas quenching on a production basis. The formation of this constituent on the surface seems to depend as much on the carburizing activity of the gas as on the ammonia content; and when this constituent is formed either with oil or gas quenching, it will be file hard after subsequent tempering at 800 F. The

* President, The Dow Furnace Company, Detroit

Prepared for the Subcommittee on Carburizing

factors that govern the depth and hardness of this layer are not fully known. Depths of several thousandths of an inch have been attained and, when properly treated, such cases are extremely hard to the file, yet do not spall. The constitution of this layer is still unknown. It should not be confused with a similar-looking but apparently quite different layer formed with higher concentrations of ammonia at temperatures usually below 1450 F.

Cases formed by this high-ammonia, low-temperature treatment can vary markedly, not only in hardness but also in tendency to spall, and should be specified with care, from the standpoint of cost and of consistent quality.

The Ford Motor Company laboratories have done creditable work on the complicated problem of determining the constitution and variations in structure that appear in cases formed in high concentrations of ammonia (10 to 20%) at approximately 1400 F. This research, based mainly on X-ray diffraction, using the powder technique, indicates that in a case with a tendency to spall, a body-centered cubic structure is predominant, and that this constituent is probably a solid solution of nitrogen in ferrite. These investigators have observed that cases not inclined to spall usually contain both close-packed hexagonal and face-centered cubic constituents and show higher penetration hardness if the hexagonal structure predominates.* It is not certain that the hexagonal and the face-centered cubic constituents are present in cases formed above 1450 F and cooled in an air blast.

There is a need for research concerning the constitution and physical properties of these outer layers and the conditions under which they are formed. Carbonitriding is still in the experimental stage, although 40 or 50 continuous furnaces, with outputs ranging from 500 to 2000 lb per hr, are in daily use, and an increasing number of batch furnaces are employed for such processing.

Nitriding

By V. O. Homerberg*

THE NITRIDING PROCESS consists in subjecting machined and heat treated steel to the action of a nitrogenous medium—commonly ammonia gas—under certain conditions to be described later, whereby high surface hardness is imparted to the steel without necessitating any further treatment.

Nitriding can be accomplished with a minimum of distortion, because of the low temperature at which the parts are case hardened and because no quenching is required after exposure to the ammonia gas. Great wear resistance, retention of hardness at elevated temperature, increased endurance limit and resistance to certain types of corrosion are other properties imparted to steel by nitriding.

The particular alloy steels that are used for nitriding are known as nitralloy. They contain aluminum as one of the alloying elements. Compositions of the most commonly used nitriding steels are listed in Table I.

Table I. Compositions of Nitriding Steels
(All these steels contain 0.85 to 1.20% Al)

Steel	Composition, percentage C	Cr	Mo
Nitralloy 125 (Type H)	0.20 - 0.30	0.90 - 1.40	0.15 - 0.25
Nitralloy 135 (Type G)	0.30 - 0.40	0.90 - 1.40	0.15 - 0.25
Nitralloy 135 modified (Aircraft Specification)	0.38 - 0.45	1.40 - 1.80	0.30 - 0.45
Nitralloy N (3½% Ni)	0.20 - 0.27	1.00 - 1.30	0.20 - 0.30
Nitralloy 230 (Alamo)	0.25 - 0.35	.....	0.60 - 1.00
Nitralloy EZ (0.15 to 0.25% Se) (Type G with Se)	0.30 - 0.40	1.00 - 1.50	0.15 - 0.25

Note All these steels contain 0.20 to 0.40% Si and 0.40 to 0.70% Mn, except Nitralloy EZ, which contains 0.50 to 1.10 Mn.

Condition of Steel for Nitriding. Nitrided parts neither warp nor distort to any appreciable extent provided the residual stresses resulting from the machining and heat treating are removed before nitriding. Nitralloy should possess a sorbitic structure before nitriding. The steel is generally purchased in the heat treated condition. This is desirable whenever the articles are to be machined directly from bar stock. It is not necessary to use heat treated stock when forgings are to be made, since they must be heat treated after forging in order to refine the grain structure and to make them machinable.

Enough of the heat treated stock must be removed to eliminate all traces of decarburization; otherwise the case produced during nitriding will be very brittle at the surface and will tend to spall. Before nitriding, the steel should be reheated to a sufficiently high temperature (generally 1100 to 1300 F depending on the core hardness desired) to remove stresses that are produced during the rough machining. This reheating is generally done before the final machining or grinding operation.

A forging temperature of 1950 to 2200 F is commonly used. Quenching in a suitable medium, followed by tempering at 1100 to 1300 F, is common practice for producing a sorbitic structure suitable for machining and nitriding. Small sections up to 1 in. in diam or thickness are quenched in oil, while large sections are generally quenched in water from 1700 to 1750 F. In general, a Brinell hardness number of approximately 225 to 250 produces satisfactory machining properties.

For annealed forgings, the steel should be rough machined, then heat treated so as to have a sorbitic structure, after which the final machining or grinding is performed. Enough stock should be left for this final operation to ensure the complete removal of the decarburized layer that is produced during the heat treating operation.

Typical procedures to be followed for annealed, heat treated and forged nitralloy 135 and nitralloy 135 modified, are given below:

Procedure 1

Nitralloy 135 and 135 modified, in the annealed condition

1 Rough machine the annealed material. Leave at least $\frac{1}{32}$ to $\frac{1}{16}$ in. on a side for final machining after heat treating. The annealing can be performed by heating to 1700 F, and then cooling slowly. The material can also be softened by subjecting hot rolled bars to a subcritical anneal at 1250 to 1300 F.

2 Heat to between 1700 and 1750 F. Quench in oil or water, preferably water when sections exceed 1 in. in thickness or diameter. The recommended times at temperature for various sections, if heated slowly

to the quenching temperature, are approximately as follows:

1 in. or less	½ hr
1 in. to 2 in. inclusive	1 hr
2 in. to 3 in. inclusive	1½ hr
3 in. to 4 in. inclusive	2 hr

3 Temper at 1100 to 1300 F, depending on the desired core hardness. Hold at temperature for 1 hr or more, depending on size of section. At least 1 hr per in. of thickness is recommended.
4 Finish machine or grind.
5 Nitride.

Procedure 2

Parts machined from heat treated bar stock

1 Rough machine. Leave about ⅛ in. on a side for finish machining or grinding. In many instances only a few thousandths of an inch may be necessary.
2 Stress relieve by reheating to between 1100 and 1200 F. Hold at temperature for 1 hr or more, depending on size of section. Ample time for stress relieving should be allowed whenever this operation is necessary; this is especially important when freedom from distortion during nitriding is desired.
3 Finish machine or grind.
4 Nitride.

Procedure 3

Parts machined from forgings

Anneal forgings by heating to 1700 F. Then after slow cooling, follow the operations given in *Procedure 1*.

Alternate Treatment

1 Normalize the forgings by heating to 1800 F, and cooling in still air.
2 Heat to between 1700 and 1750 F, and quench in oil or water, preferably water, when the sections exceed 1 in. in thickness or diameter.
3 Temper at 1100 to 1300 F, depending on the desired core hardness.
4 Rough machine.
5 Finish machine.
6 Nitride.

Mechanical Properties. The mechanical properties of several nitralloy compositions are given in Tables II, III and IV. Standard specimens (0.505-in. diam and 2-in. gage length) were used for the tension tests.

Effect of Size on Mechanical Properties. The mechanical properties will vary with the size of section. Tables V and VI present the results of tests in which the specimens were taken longitudinally, as nearly as possible halfway between the center and the edge of the piece.

Judgment is required in using the tables given above. The mechanical properties will vary not only with the compositions of different heats of steel but also with the size of section. The properties given in Tables II, III and IV were obtained with sections not exceeding 1 in. in diam. Frequently specifications give minimum values.

Nitralloy 135 modified is widely used by the aircraft industry. U. S. Army Specification 57–107–28A requires the minimum mechanical properties given in Table VII. This specification states that the mechanical properties given in Table VII shall be met after quenching in oil or water from 1725 to 1750 F, and then tempering at a temperature not lower than 1100 F for 5 hr. Sizes up to 2 in. are quenched in oil; sections greater than this may be quenched in water.

The quenching temperature used in establishing the values given in Table VII was 1725 F, and the tempering temperature 1200 F. The 3-in. and 5-in. bars were water quenched. The test specimens were taken from the heat treated bars midway between center and edge.

Nickel Nitriding Steels. Nickel in nitralloy strengthens and toughens the case with a moderate decrease in case hardness; it also strengthens and hardens the core and thereby provides better support for the case. In steels that contain appreciable proportions of aluminum, nickel causes dispersion hardening, by means of which articles may acquire higher core strength and elastic properties during nitriding.

A typical example of the properties of nitralloy N is shown in Table VIII. The steel was quenched in oil from 1650 F and was then tempered at 1200 F.

Before nitriding, lower hardness can be obtained by tempering at a temperature higher than 1200 F, in order to promote machinability without affecting the final hardness of the core. The steel should not be tempered below 1100 F; otherwise precipitation hardening will take place, thereby rendering the steel difficult to machine. The precipitation hardening should occur only during nitriding.

Nitriding of Steels with High Core Hardness. Special steels must be used for applications that require a high

Table V. Effect of Size on Mechanical Properties of Nitralloy 125[a]

(a) Composition: 0.35% C, 0.60% Mn, 0.22% Si, 1.30% Cr, 0.25% Mo, 0.94% Al. Bars were quenched in water from 1725 F.

Table VII. Minimum Mechanical Properties Specified for Nitralloy 135 Modified

Size of Section	Tensile Strength psi, min	Yield Strength psi, min	Percentage Elongation in 2 in. min	Percentage Reduction of Area, min	Brinell Hardness Number	Extension under Load, in. in 2 in.[a]
Up to and including 1½ in.	135,000	100,000	16	50	280 to 340	0.011
1½ to 3 in.	125,000	90,000	15	40	280 to 340 (on surface) 269 to 321 (on test specimen)	0.011
3 to 5 in.	110,000	85,000	15	40	269 to 321 (on surface) 240 to 300 (on test specimen)	0.010

(a) In high-carbon steels, alloy steels and cold worked steels, yielding is so gradual that there is no sharp break, hence no definite yield point. It is customary to adopt an arbitrary amount of permanent strain that is considered admissible for general purposes. This is the strain value given in column 7, and the stress at which this occurs is the yield strength given in column 3.

core hardness to support the nitride case. The compositions and nitriding data for a number of steels of this type are given in Tables IX and X. These steels were heat treated in accordance with the recommendations of the manufacturers. The data for nitralloy N are included, since this steel has a high core hardness after nitriding. Nitralloy N and steel B are the ones most commonly used when high core hardness is required.

Nitriding of Stainless Steels. Considerable attention has been given to the nitriding of stainless steels, especially steels of the austenitic type. An austenitic steel (0.45% C, 14% Ni, 14% Cr, 2.5% W and 0.30% Mo) is used widely and advantageously for exhaust valves in aircraft engines, because the stems of the valves can be nitrided.

Since the protective oxide film present on the surface of the stainless steels, inhibits nitriding, this film should be removed by pickling or should be reduced by active hydrogen or other suitable agent before nitriding.

A somewhat prevalent belief is that stainless steels can be nitrided to produce a hard surface without any loss of resistance to corrosion. This is not true, since the resistance to corrosion depends on the existence of a suitable amount of chromium in solid solution. During nitriding, the chromium at the surface is precipitated as submicroscopic particles of chromium nitride; consequently the material has considerably less resistance to corrosion.

Nitriding of SAE and Similar Steels. Chromium-molybdenum-nickel and other medium-carbon steels that do not contain aluminum are being nitrided extensively. Although, after nitriding, such steels have a hardness considerably lower than that of steels containing aluminum, nevertheless these SAE steels exhibit improved resistance to wear, increased endurance limit and nonseizing properties superior to those of the same steels when not nitrided.

The Nitriding Process. Nitriding, as carried on commercially, consists in subjecting the heat treated articles to the action of ammonia gas at temperatures ranging from 930 to 1200 F. The most commonly used temperature is between 930 and 1000 F.

Nitriding Equipment. Although special furnaces for nitriding are now being built, the essential requirement is that the furnace must maintain a uniform temperature within the nitriding container.

Table VIII. Mechanical Properties of Core, Nitralloy N[a]

Property	Before Nitriding	After Nitriding
Yield strength, psi	114,600	180,000
Tensile strength, psi	132,400	190,250
Elongation, % in 2 in.	22	15
Reduction of area, %	59.4	43.4
Brinell hardness number	277	415

(a) Quenched in oil from 1650 F; then tempered at 1200 F

Nitriding furnaces may be of the batch, semicontinuous or continuous type. The first two types are in general use.

Ammonia Gas. The tank of ammonia must be placed in such a position that the bent tube inside the tank has its open end in the gaseous atmosphere and does not dip into the liquid ammonia. The use of a suitable needle valve ensures the control of a steady and even flow of gas. Although anhydrous ammonia is a commercial product, final traces of water can be removed by passing the gas through a tower that contains lime. The inlet and outlet tubes are made of nickel or inconel, and the articles in the container are supported preferably on screens made of nickel or nickel alloy. The gas mixture from the container passes through a wash bottle to indicate the back pressure (which should be about 1 to 2 in.) as well as the rate of flow of the gas, and finally passes into the atmosphere or is washed into a drain by means of a suitable baffle.

Ammonia gas decomposes to a certain extent into nitrogen and hydrogen, according to the following reaction: $2NH_3 = 2N + 3H_2$. Nitrogen, which is very active at the moment of the decomposition of the gas, combines to a certain extent with the alloying elements in the steel to form nitrides. These nitrides, in a fine state of dispersion in the case, impart extreme hardness to the surface of the steel, a hardness that gradually decreases inwardly until it corresponds to that of the core.

The gas mixture leaving the furnace consists of hydrogen, nitrogen and undissociated ammonia. The ammonia gas has high solubility in water, whereas the hydrogen and the nitrogen are insoluble, a circumstance that is used advantageously in the determination of the extent of the ammonia dissociation during nitriding.

Floe studied the depth-hardness characteristics and microstructures after varying the dissociation from 15 to 85%. He found that an appreciable saving in ammonia and an improvement in the surface of the case could be accomplished by keeping the dissociation at 30% for several hours and then permitting it to increase to 75% while the flow of ammonia was kept constant. The increase in dissociation is caused by catalytic action of the nitride case.

Containers for Nitriding. The question of suitable container materials and the methods of sealing have received considerable attention. Unfortunately, low-carbon steel absorbs nitrogen and the inside surface of the container becomes embrittled. Besides embrittling the container, the nitrided surface is also believed to have a harmful influence in catalyzing the decomposition of the ammonia in contact with it and thereby preventing the proper nitriding of the articles. The atomic nitrogen in immediate contact with the steel parts is responsible for the nitriding.

Enameled low-carbon steel containers have been used successfully, since the enamel coating presents an inert surface. Such a coating

Table IX. Compositions of Steels for Which Properties are Listed in Table X

Nitriding Data for Steels Having High Core Hardness

(*See* Table IX for the compositions of these steels.)

Steel	Nitriding Temperature, deg Fahr	Nitriding Time, hr	Vickers Hardness, (10-kg load)	Depth of Case, inches	Core Hardness, Rockwell C
A	975	72	975	0.018	47
B	1000	48	1150	0.012	59
C	1000	72	970	0.012	50
D	1000	72	1400	0.015	63
E	1000	48	925	0.008	56
F	1000	48	975	0.018	47
G	900	48	1100	0.014	43
Nitralloy N	975	35	1064	0.016	44

however, has a number of objectionable characteristics. It is easily chipped and may spall at the nitriding temperature because of the pressure of the gases within the steel. The articles to be nitrided must be carefully handled so that the enamel will not be chipped or cracked.

High-chromium and high-nickel alloy containers are being used successfully. Two of them have the following approximate compositions: 80% Ni, 14% Cr, 6% Fe (inconel); and 25% Cr, 20% Ni, remainder iron. Welded containers made from these two materials—especially the former—are giving excellent service.

Depth-Hardness Data. Typical depth-hardness curves for several nitralloy compositions after nitriding are shown in Fig. 1. The effect of the tempering temperature on the depth-hardness of nitralloy 135 modified is shown in Fig. 2.

The hardness testing machines most commonly used for testing the hardness of nitrided steels, are the Rockwell superficial hardness tester (15-kg or 30-kg load) and the Vickers hardness tester (usually 10-kg load). The regular Rockwell tester using the A scale, is also being employed.

Growth During Nitriding. Articles increase slightly in size during nitriding. This growth depends mainly on the temperature and the duration of nitriding, although the structure of the steel is also a factor. In parts larger than 1 in. in section or diameter, a sorbitic structure with no free ferrite is difficult to procure. As a result, the larger the section, the greater is likely to be the growth. Absence of decarburization is of vital importance since the nitriding of a decarburized surface produces not only excessive growth but also a brittle case. The amount of growth is constant under identical conditions, so after it has once been determined for a given material or article, growth can be allowed for in the final machining or grinding, or it can be removed by lapping or careful grinding of the nitrided part. An increase in diameter of 0.002 in. in a specimen that has a case depth of 0.030 in., is representative.

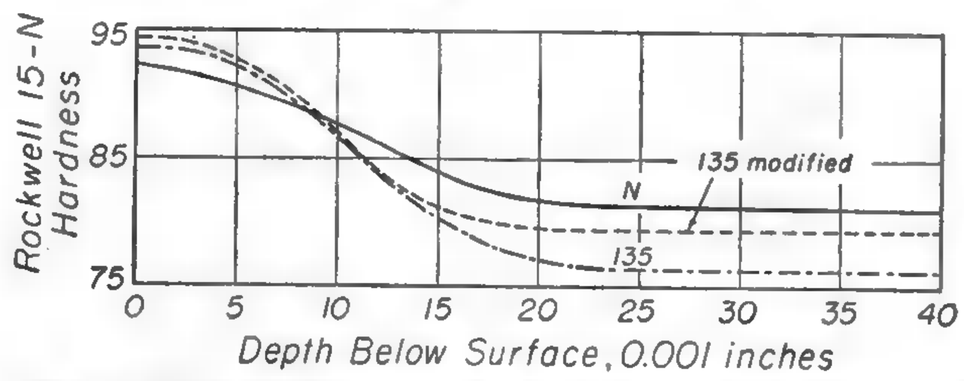

Fig. 1 Depth-hardness of nitrided nitralloy 135, 135 modified and N. Nitralloys 135 and 135 modified were quenched in oil from 1725 F, and tempered at 1250 F. Nitralloy N was quenched in oil from 1650 F, and tempered at 1200 F. All three steels were nitrided at 975 F for 48 hours. Compositions were as follow:

Nitralloy	Composition, percentage						
	C	Mn	Si	Cr	Mo	Al	Ni
135	0.35	0.56	0.36	1.18	0.20	1.07	....
135 modified	0.41	0.58	0.28	1.73	0.36	1.10	....
N	0.27	0.67	....	1.24	0.25	0.92	3.60

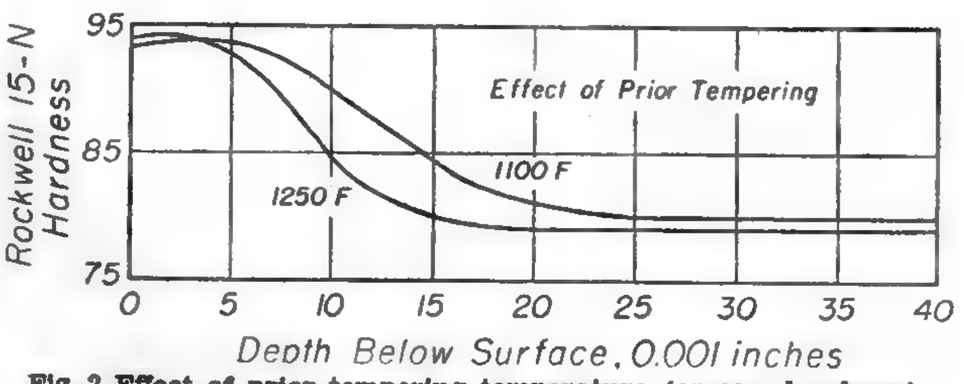

Fig. 2 Effect of prior tempering temperature (or core hardness) on the depth-hardness characteristics of nitralloy 135 modified. Samples were nitrided at 975 F for 48 hours.

Protection Against Nitriding. Tin plating is an excellent means for providing protection. A plating of 0.0003 in. will protect the parts and will not run. Bronze and copper plating are also being used successfully. A protective

Table XI. Coefficient of Linear Expansion of Nitralloy

Nitralloy 135 Modified, Not Nitrided		Nitralloy 135, Nitrided	
Temp, deg Cent	cm per deg Cent	Temp, deg Cent	cm per deg Cent
0 to 100	0.00001184	0 to 100	0.00001214
0 to 200	0.00001188	0 to 200	0.00001218
0 to 300	0.00001192	0 to 300	0.00001222
0 to 400	0.00001196	0 to 400	0.00001226
0 to 500	0.0000120	0 to 500	0.0000123

For mild steel (0.25% C) the coefficient of linear expansion from 0 to 200 C is 0.0000115 cm per deg Cent.

paint known as Sel-Nite gives satisfactory results. Care should be taken to permit the paint to dry before the parts are placed in the furnace.

Distortion. Many parts can be nitrided without appreciable distortion. Such parts are of uniform section and have been treated so that no machining stresses are present. The stresses produced by rough machining are removed by reheating the parts between 1100 and 1200 F before final machining or grinding. The time at temperature varies with the articles. Usually a period of 1 to 4 hr at temperature is sufficient. Slight distortion may occur in other sections because of unequal growth. The nitriding of a water-pump spindle with a long keyway on one side, can be cited as an example. Such a part tends to bow during nitriding, with the keyway at the top of the arc. This can be explained by the fact that a greater area adjacent to the keyway is exposed to the nitriding gas than on the opposite side and in consequence greater growth takes place, with attendant distortion. If the keyway has been protected against nitriding, the nitriding treatment tends to bow the part slightly in the opposite direction, because no growth takes place on the protected portion. Parts of this kind are generally straightened hot after nitriding.

Slightly distorted parts can be straightened either cold or hot, but hot straightening is preferred. Straightening, especially when it is done cold, should be performed with caution, in order not to crack the case. Fatigue failures may result from any cracks at vital points in parts that must resist alternations of stress or a repeated stress. The presence of such cracks will also result in failure to withstand corrosion. Since no softening of the case takes place when a part is heated at 1200 F for a short time, it is entirely safe to heat to this temperature for straightening. A typical procedure is to heat the part to 1200 F and then to straighten it in a press, using a copper shoe for distributing the load. The complete removal of residual stresses before nitriding and the proper placing of the parts in the nitriding container, will greatly lessen the possibility of warping or distortion.

Surface Defects. If the decarburized surface is not removed before nitriding, the case will spall very readily. This condition may be caused by improper centering during the machining, so that an insufficient amount of material is removed from some points. When parts are coated with rolling or forging scale, $\frac{1}{32}$ to $\frac{1}{16}$ in. of material must be removed in order to eliminate the decarburized layer.

Softening. Occasionally it is desirable to soften the case of nitrided parts in order to make changes in design. This softening can be accomplished by heating the nitrided parts in a fused bath consisting of a mixture of 50% each of sodium and potassium chlorides at a temperature of 1500 F, thus causing the nitrides to decompose. Softening the case by annealing at 1800 F has also been recommended and will render the material machinable, but renitriding will not restore the original hardness.

Neither method will produce entirely satisfactory results. For ensuring satisfactory results, the softened layer should be completely removed before renitriding. Such a procedure prohibits a softening process for finished articles.

Retention of Hardness of Nitride Case. One of the valuable characteristics of nitrided nitralloy is retention of hardness at elevated temperatures. The material can be heated for long periods of time at 1000 F and for short periods at 1200 F, without producing any softening of the case. The case of nitrided nitralloy is just as hard when tested at 750 F as at room temperature. This retention of hardness makes the material of great value for many applications, especially where lubrication may be faulty.

Coefficient of Expansion. Data concerning the thermal expansion of nitralloy 135 and 135 modified, are shown in Table XI. The Firth-Brown Research Laboratory reports the coefficient of expansion of the case (as distinct from the core) to be as follows:

Temperature, deg Cent	Coef Exp per deg Cent	Temperature, deg Cent	Coef Exp per deg Cent
20 to 100	0.0000107	20 to 400	0.0000123
20 to 200	0.0000113	20 to 500	0.0000129
20 to 300	0.0000118		

Endurance Properties of Nitrided Nitralloy. Since nitrided nitralloy is frequently used in applications where it is subject to a repeated stress, the effect of nitriding on the endurance properties is of considerable importance. A number of investigations give results that are in agreement and show that the effect of nitriding is to increase the endurance range as determined by reversed bending. Fatigue failures do not begin at the surface but at the junction of the case and the core, indicating that the endurance of nitrided parts is controlled to a considerable extent by the characteristics of the core.

Surface features that lead to stress concentrations, such as notches, threads and scratches, have a much slighter effect in nitrided material than in unnitrided material.

The results of rotating-beam fatigue tests performed by a number of investigators are summarized in Table XII.

Not nitrided	138,900	73,900	40,300 to 41,400	45,900 to 47,000
Nitrided for 60 hr	.....	87,400 to 88,500	87,400 to 88,500[c]	87,400 to 88,500

(a) 0.004 in. deep, as sharp as possible; notched before nitriding
(b) At the joint of test length (0.30-in. diam) to ends (0.48-in. diam). Samples finish machined before nitriding
(c) Specimens did not break at notch.

In fatigue tests conducted by Sutton, an examination of the fractures of Wohler test specimens indicated that the cracks originated at a point near the junction of the case and the core, but within the core material. His results indicate that, in a nitrided specimen, fatigue fracture occurs when the stress exceeds the fatigue limit of the core, at a point near the junction of the case and the core. Therefore the permissible loads on nitrided specimens are ordinarily limited by the fatigue properties of the core. Since fatigue cracks in nitrided parts do not begin at the surface, small surface defects are not so important as in hard steels of other types.

In a rotating-beam type of fatigue test, a nitrided specimen that had been notched to a depth of 0.004 in. by grinding, remained unbroken after being subjected to a test at a stress range of ±71,700 psi, but failed at ±88,500 psi at an undamaged place, since the origin of the fracture was in the core. A turned notch 0.004 in. deep that was cut before nitriding, had no effect on the fatigue strength, but the same notch on a specimen that had not been nitrided, reduced the fatigue strength by 45%.

For results of fatigue tests, see Table XIII.

V-notches in the case do not reduce the fatigue limit, provided the notches are cut before nitriding.

Nitrided steels may be expected to retain their high endurance value at temperatures as high as 800 to 1000 F, because the hardness and strength values of the case are not affected greatly by these temperatures.

Bittel* tested heat treated nitralloy 135 modified, in a Rayflex fatigue-testing machine in which the specimen is vibrated at a controlled amplitude in the natural frequency of the sample.

The Brinell hardness number of the steel was 269. The specimens, 18 in. long and ½ in. in diam, were ground, polished and nitrided at 975 F for 40 hr.

A series of tests was made first on the heat treated material. In order to determine the effects of notches on the endurance limit, a circumferential groove was machined 0.010 in. deep, with radius 0.005 in. and an included angle of 50 deg, in the center of one set of specimens. A V-notch 0.010 in. deep, with radius 0.005 in. and an included angle of 60 deg, was machined in a second set of specimens. The endurance limit was determined for each set of nitralloy specimens before nitriding and after nitriding. Table XIV gives the results of the investigation.

Wear Resistance of Nitrided Nitralloy. Since the nitride case loses none of its hardness when tested at temperature, until heated above 750 F, it possesses marked advantages over case hardened and other hardened steels, which soften when heated to this temperature. Nitrided nitralloy is therefore less susceptible to galling and scoring than these steels. A number of industrial applications involve the use of nitrided nitralloy parts against other nitrided nitralloy parts, under conditions where faulty lubrication may be experienced and consequently a marked increase in temperature.

* F. J. Bittel, The Effect of Notches on the Fatigue Strength of Nitralloy, Thesis M.I.T., 1940

Table XIV. Endurance Limit of Nitralloy, Unnitrided and Nitrided

Condition	Endurance Limit, psi
Unnitrided without notch	45,000
Nitrided without notch	90,000
Unnitrided with half-circle notch	25,000
Nitrided with half-circle notch	87,000
Unnitrided with V-notch	24,000
Nitrided with V-notch	80,000

Leaded and graphite bronzes are generally used as bushings to run against nitrided nitralloy. A bronze containing 80% Cu, 10% Sn and 10% Pb is suitable for the purpose.

Nitrided nitralloy is used widely for cylinder barrels of high-power aircraft engines; the excellent resistance of nitralloy to wear, along with its other characteristics, makes it a satisfactory material for this purpose.

Creep Tests on Nitrided Nitralloy. Nitrided nitralloy has been tested by Malcolm under a load of 10,180 psi. After 4000 hr the extension amounted to 0.002 in. per in. with no further extension during 5000 hr more at 1000 F.

Resistance to Corrosion of Nitrided Nitralloy. Although the resistance to corrosion of nitrided nitralloy has been studied by a number of investigators to show that this material strongly resists the action of alkalies, atmosphere, crude oil, tap water, still salt water and combustion products of natural gas, it must be understood that nitrided steels do not resist corrosion as effectively as stainless steels. The outermost part of the case exhibits maximum resistance to corrosion and for that reason the parts should be left as nearly as possible in the condition in which they come from the nitriding furnace. The removal of part of the case will greatly decrease the resistance to corrosion. Nitrided nitralloy will not withstand the corrosive action of mineral acids.

Welding of Nitralloy. Nitralloy can be welded successfully by the atomic hydrogen process and by flash welding. A welding rod made of nitralloy should be used in the atomic hydrogen process. After nitriding, no appreciable difference is evident between the hardness at the weld and the hardness away from it.

Determination of Ductility of Case of Nitrided Nitralloy. The character of the impression produced by the various hardness-testing machines is indicative of the ductility of the case. If the impression is free from spalled edges, the nitride case is more ductile than one in which the edges are not well defined. The ductility of the nitride case can be determined qualitatively with the Brinell machine, by observing the load necessary to crack the case.

After experiments with a number of different methods, it has been found that the torsion test gives more significant results for ductility than other mechanical tests.

Aluminum Impregnation

By B. J. Sayles*

CALORIZING is a trade name for a process of alloying the surface of carbon or alloy steel with aluminum by diffusion. The depth of penetration varies from 0.005 to 0.040 in., but on thin articles is usually 0.025 to 0.030 in. The surface layer of iron-aluminum alloy usually contains approximately 25% Al.

Methods. The old-style powder method was in general commercial use until 1935. The articles were packed in a powder compound, of which the active ingredient was powdered aluminum, together with a small proportion of ammonium chloride, and were then sealed gastight in heated revolving retorts in which a neutral atmosphere was maintained. Duration of treatment was usually 4 to 6 hr at 1550 to 1700 F. The resulting aluminum-iron surface alloy, about 60% Al, was 0.001 to 0.006 in. deep.

The surface alloy layer gave excellent resistance to heat and to corrosion by sulfurous gases, but was brittle and inclined to spall whenever the article was subjected to mechanical abuse, for instance by a rotary tube cleaner.

Modern Powder Calorizing.[1] Since 1935 both the foregoing method and a new method have been used for securing an initial aluminum-iron alloy layer. After removal from the retort, the work material is subsequently heat treated for periods of 12 to 48 hr at temperatures from 1500 to 1800 F, to cause further penetration of the aluminum by diffusion to depths ranging from 0.025 to 0.040 in. Since no compound is in contact with the work during the heat treatment, the aluminum content of the surface is decreased. The usual content of 25% Al or less is ample to ensure good resistance to heat and corrosion. Because of the lower aluminum content, the surface alloy layer exhibits toughness and ductility not obtainable by the older process.

Pack Calorizing. This method consists in packing the work material, along with the powdered aluminum compound, in stationary boxes that are then sealed tight and heated. The process requires from 6 to 24 hr at temperatures ranging from 1500 to 1800 F. Since the process is a combination of aluminizing and diffusion heat treatment, no further treatment is needed after the metal has been removed from the container. Pack calorizing is recommended especially for articles of light gage or irregular shape that might be damaged by processing in a rotating retort.

Dip Calorizing. In this method the article is coated by dipping in molten aluminum in a manner analogous to hot dip galvanizing. (For details, see page 704.) The coating consists principally of aluminum with only a thin layer of bonding alloy. The *Fink Process,* characterized by treatment in a hydrogen atmosphere just before the immersion in molten aluminum, is readily adaptable to the treatment of wire or strip, which can be passed continuously through a hydrogen tunnel.

Martin Process. The surface layer of aluminum-iron alloy is formed, in this process, by treating the metal in aluminum chloride vapor at a high temperature. It is reported that the surface alloy thus obtained is shallow compared with the coating produced by the other processes.

Metal Spraying. See page 720 for information concerning the spraying of molten aluminum.

Resistance to Oxidation. Calorized steel is highly resistant to oxidation and to corrosion by flue gas at high temperature. This can be attributed to the formation of a surface film of aluminum oxide, which is self-replacing as long as any appreciable amount of aluminum remains at the surface. Calorized parts remain serviceable for years at temperatures not exceeding 1400 F. Such parts, however, are often used at temperatures up to 1700 F for purposes where the usual life of the part (for example, a heat treating pot) is long enough to justify the higher cost as compared with that of carbon steel. Table I gives the relative resistance to oxidation of some steels before and after calorizing.

Resistance to Corrosion by Sulfurous Gases. One type of resistance to corrosion that is important commercially, is immunity to the attack of various kinds of sulfurous gases—H_2S, SO_2, SO_3—found in furnace flue gases at fairly high temperature. Calorized articles may be used in furnaces that employ fuels high in sulfur. Calorized steel has been accepted widely in oil refineries and in heat exchangers for contact sulfuric acid converters. Calorized steel is rapidly attacked, however, by aqueous solutions

of mineral acids and, hence, is not suitable at the low-temperature end of the furnace ducts, where condensation of water vapor in the flue gases is favorable to the formation of sulfurous acid.

Calorizing improves the resistance of steel to corrosion in hydrogen sulfide, as is indicated in Table II. The test was conducted in a muffle type of furnace with hydrogen sulfide flowing continuously at atmospheric pressure.

Table II. Resistance to Corrosion in Hydrogen Sulfide

Increase in weight (mg per sq cm) during 24 hr at 1200 F

Nominal Composition of Steel	Not Calorized	Calorized
0.08 – 0.18% C, 18% Cr, 8% Ni	36.5	0.1
0.08 – 0.18% C, 0.30 – 0.60% Mn, 5% Cr, 1% W	175.6	0.5
0.08 – 0.18% C, 0.30 – 0.60% Mn, 5% Cr, 0.50% Mo	172.8	1.3
0.08 – 0.18% C, 0.30 – 0.60% Mn, 5% Cr	183.4	0.5

0.08 – 0.18% C, 0.30 – 0.60% Mn, 1.25% Cr, 0.50% Mo	101.3	0.7
0.08 – 0.18% C, 0.30 – 0.60% Mn, 0.50% Si max	173.5	0.6

Creep Strength at High Temperature. Calorized coatings, by protecting the base metal from reduction in cross section through oxidation, extend the useful, working range at high temperature of many low-priced steels that have low resistance to oxidation. As an example, a killed carbon steel containing 0.08 to 0.18% C, 0.30 to 0.60% Mn and 0.50% Si, required, before aluminum impregnation, 1400 psi stress to produce 1% creep in 10,000 hr at 1100 F. Calorizing this steel increased the stress to 2050 psi, under the same condition of test.

Ductility. The aluminum-iron surface alloy is hard, but is sufficiently tough to exhibit about 5% elongation before the development of surface cracks. This enables the surface alloy to bend with the steel when hot, and the product is not subject to cracks under stresses within commercial limits.

Fabrication. Except with thin coatings low in aluminum content, like coatings employed on automobile exhaust pipes, cold fabrication of aluminum impregnated steel is not practicable. Usually, bending and forming must be performed at a bright red heat, but unless the bending radii are liberal, cracking may occur. Calorized steel will withstand about 5% elongation before surface fissures appear.

Uses. Calorized metal is used for pots for salt, cyanide, and lead, preferably operating at a bath temperature not higher than 1550 F; bolts for use at temperatures up to 1400 F; tubes for air heaters, radiant steam superheaters, oil and gas polymerizers; furnace parts to be used at temperatures up to 1400 F; glass lehrs and furnaces for heating nonferrous alloys.

Hot Dipped Aluminum Coatings on Steel

By B. P. Finkbone*

ALUMINIZING is a relatively new method of applying a nonferrous protective coating to a metal, usually iron or steel, by hot dipping. After being suitably prepared, the iron or steel is passed through a bath of molten aluminum alloy, and the coating is allowed to solidify on the surface. This coating can be applied to sheets, strip and wire.

Aluminum owes its corrosion resistance to the existence of a self-renewing film of surface oxide that forms in air. The aluminum coating provides the resistance to corrosion and to heat, the heat reflectivity, and the attractive appearance of aluminum; the base metal gives the strength and other mechanical properties of iron or steel. Under many conditions the aluminum coating, like zinc, affords galvanic or electrolytic protection on bare spots, by sacrificing itself as the anode to reduce corrosive attack of the exposed steel base metal, the cathode.

Base Metals. Aluminum coating is applied commercially to mild steel, copper steel and low-alloy high-strength steel. When sheet steel is needed for superior drawing qualities and more uniform workability, drawing quality may be specified.

Table I lists some mechanical properties of steel that has been coated with aluminum by hot dipping.

* Products Engineer, Research Laboratories, American Rolling Mill Company, Middletown, Ohio

Weight of Coating. The weight of an aluminum coating on sheet or strip usually is approximately 0.50 oz per sq ft. The coating thickness is approximately 0.001 in. per side or 0.002 in. over-all on sheet and strip. This is approximately equivalent in thickness to a 1.30-oz coating of zinc. The difference in coating weights results from the different specific gravities of the two metals.

Table I. Mechanical Properties of Aluminized Steel

Property	Low-Carbon Steel Base	High-Strength Steel Base
Yield point, psi	40,000	50,000 to 60,000
Tensile strength, psi	50,000	65,000 to 80,000
Elongation, % in ▮ in	10 to 25	12 to 20
Rockwell B hardness	75 max	70 to 85 max

Fabrication. Aluminized steel can be fabricated by all the conventional processes, including punching, shearing, and forming on a press brake, and can be drawn moderately or stamped if the article to be drawn or stamped is designed with large radii to relieve friction, strain and sharp corners. Such drawing should be done on a slow-action press.

Aluminized steel can be joined by any one of several methods: double seaming, arc welding, seam or spot welding, oxyacetylene welding, or brazing. Certain precautions

are necessary, similar to those employed in joining aluminum. During the welding operation excessive oxidation of the coating must be prevented; and in spot and seam welding, it is desirable to remove the film of aluminum oxide from the surface before welding. The material can be soldered after the edges to be joined have been suitably prepared.

Heat Resistance. Up to about 900 F, the aluminum coating gives complete protection to the steel beneath it without discoloration. Above 900 F the coating reacts with the steel base to form an aluminum-iron alloy that is tightly adherent and highly refractory. Tests have shown that this aluminum-iron alloy completely protects the steel base from oxidation and scaling during short exposures to temperatures as high as 1750 F.

Heat Reflectivity. Aluminized steel will serve as an efficient and stable reflector of heat and light. The superior heat-reflecting quality is preserved by the resistance of the aluminum coating to oxidation and discoloration by heat.

Superior heat-resisting and heat-reflecting characteristics make aluminum-coated sheets desirable for such uses as oven linings, heat deflectors and heating element retainers. Parts fabricated of aluminum-coated steel serve equally well in units heated by electricity, gas, oil or solid fuels.[2]

Resistance to Atmospheric Corrosion. Aluminum-coated steel is comparatively new and corrosion tests have not continued long enough so far to supply complete data concerning the resistance of the material to atmospheric corrosion.

However, tests based on four years of exposure in a mild industrial atmosphere, have shown aluminum coatings to lose approximately one-tenth as much weight as galvanized coatings under the same conditions. Exposures for two years in a marine atmosphere have shown that aluminum coatings lose approximately one-fifth as much weight as galvanized coatings. Although aluminum coatings in the outdoor atmosphere do not offer the same galvanic protection as zinc coatings at sheared edges, the rusting of edges has not been serious in the aluminum-coated samples in the above tests.

Possible Uses. Aluminized steel fills a recognized need for a relatively low-priced, heat-resistant sheet metal. In circulating heaters of advanced design, the drums or inner jackets are being made of this material in order to resist the destructive effects of high temperature.

Aluminized steel has also been used successfully in the aircraft industry, to replace less easily obtainable material in firewalls and accessories.[3]

Aluminized steel mufflers and tail pipes for gasoline engines have shown a noteworthy increase in serviceability beyond that of similar parts made of such materials as hot rolled, cold rolled and terne-coated sheets. Service of this kind demands a combination of resistance to corrosion and heat.

Chromium Impregnation

By F. C. Kelley*

CHROMIUM impregnation or "chromizing" consists in packing the metal to be treated in a mixture of powdered alumina and chromium. Alumina is used to prevent the sintering of the powdered chromium into a solid mass. The amount of each material used may be varied, but a satisfactory mixture consists of 45% dry alumina and 55% chromium by weight. The work material is usually packed in a tube or container of iron and then heated to between 2375 and 2550 F in hydrogen for 3 to 4 hr. The duration of treatment may be varied according to the penetration and concentration of chromium desired.

Atmosphere. A protective atmosphere like hydrogen, free from oxygen and water vapor, is absolutely necessary to prevent oxidation of the chromium. The particles of chromium in contact with the metal to be treated, must be kept clean to permit diffusion. The hydrogen should be pure enough to reduce chromic oxide, for this will preserve the chromium powder in the metallic state and prevent loss by oxidation. The hydrogen may be passed directly into the iron container that holds the charge. The container should be provided with a vent to allow circulation of the pure hydrogen. The atmosphere of the furnace may be commercial hydrogen with enough water and oxygen removed to protect the molybdenum winding from oxidation.

Furnace. The temperatures in this process require a furnace capable of maintaining a high temperature through a long period. An electric furnace is used that is provided with a molybdenum or tungsten winding as the heating unit; a satisfactory type of unit consists of an alundum tube wound with molybdenum wire. The tube is placed in a suitable furnace casing and surrounded with alumina powder, which acts as insulating material. The furnace casing should be tight to prevent the loss of hydrogen and the infiltration of air.

Material. The metal best suited for chromizing is low-carbon steel that contains 0.10 to 0.20% C. Steels of higher carbon content may be used if the surface is first decarburized, as by heating in hydrogen. Materials to be chromized should have a clean surface so that diffusion can take place freely. Machined parts should be free from oil, grease or soap.

Structure of Coating. The layer of chromized material on the surface of iron treated by this process, consists of large columnar grains. This structure is typical of many coatings formed on iron by diffusion processes. Elements such as aluminum, silicon, molybdenum and tin, form coatings of similar structure when diffusing into iron.

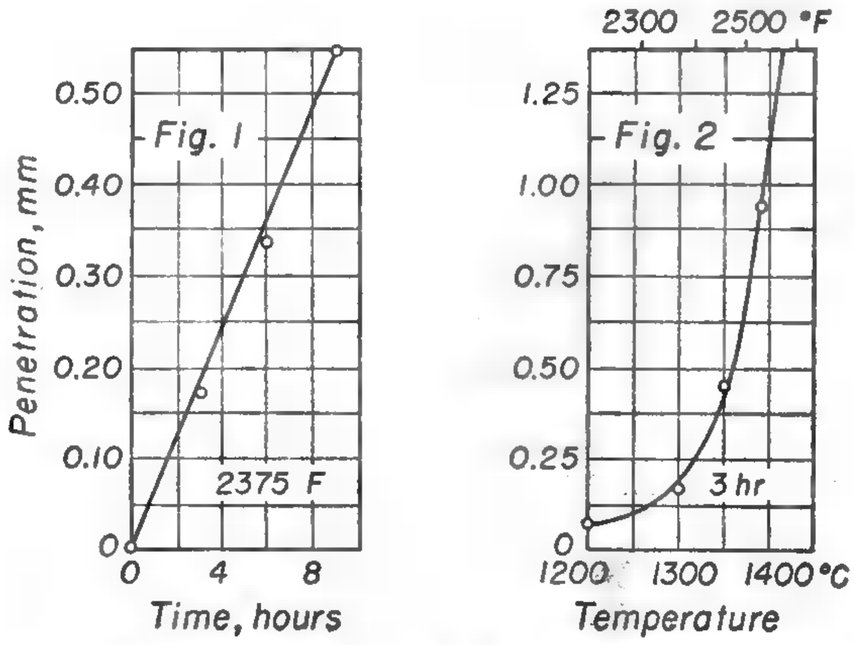

Fig. 1 Curve showing the change in penetration of chromium with the time, at 2375 F

Fig. 2 Effect of temperature on the penetration of chromium during a 3-hr period

Diffusion Rates. The penetration of the chromium with respect to time and temperature is shown by Fig. 1 and 2.

Resistance to Corrosion. Chromized iron has high resistance to corrosion in salt spray, steam and regular atmospheric conditions, and will withstand 10% nitric acid for long periods of time without discoloring the solution.

* Research Laboratory, General Electric Company, Schenectady

The chromium content of the diffused layer varies between 10 and 20%, depending on the time and temperature of heating.

Other Methods. G. Becker, K. Daeves, and F. Steinberg have utilized a reaction between gaseous chromous chloride and iron at 1000 C to produce a chromium-rich solid solution that is highly resistant to corrosion.

A mixture of H_2 and HCl is passed over chromium or ferrochromium, heated to 900 C or above, and the resulting $CrCl_2$ is passed over the material to be treated. When the gas ($CrCl_2$) comes in contact with the iron, an exchange of a chromium atom for an iron atom takes place, and the resulting $FeCl_3$ sublimes and is carried off by the hydrogen. The "valve" on this reaction, regulating the rate at which the chromium is deposited, is the rate of diffusion of iron through chromium. At 900 C this rate is slow and the diffused layer is thin.

Becker, Daeves and Steinberg have also used a ceramic material impregnated with $CrCl_2$, for packing around the article to be chromized. This method ensures uniform impregnation.

It is necessary to use low-carbon material (0.1% C or lower) to secure satisfactory coatings. The mass of the metal to be treated is most important, because the larger the mass, the greater the amount of available carbon. Elements such as titanium, columbium and molybdenum have been used in the steels to "fix" the carbon and to improve the resistance of the coatings to corrosion.

Coatings about 0.0005 in. thick are obtainable at 900 C after 3 hr. Thicker coatings are obtainable by increasing the temperature. The thin coatings obtained have been reported to contain as much as 35% Cr at the surface.

W. M. Mitchell secured a United States patent on a process for coating the surface of a steel ingot with a chromium-iron alloy. The surface of a mold is coated with chromium; sodium silicate is used as a binder. Hot metal, when poured into the mold, alloys with the coating and produces a chromium-iron alloy on the surface. The ingot can then be rolled into sheets with a high-chromium alloy on the surfaces. Castings with a high-chromium alloy on the surfaces can be made in the same way.

A British patent was granted to M. Fiedler for a process of coating a metal with a chromium-rich alloy. This process consists in electroplating chromium on the surface of steel and then heating the plated article by passing it through a high-frequency field. As a result, alloying occurs between the base metal and the chromium plate. By this process, iron pipe can be plated with chromium on the outside and then passed continuously through a high-frequency coil until heated to about 2200 F so that alloying takes place between the chromium plate and the iron.

Folliet and Sainderichin were granted a United States patent on a cementation mixture for treating ferrous articles. The components are an oxide of chromium, 2 to 10% of a chloride of chromium, and a quantity of finely divided aluminum. The aluminum content depends on the amount of oxygen in the metallic oxide used. The articles to be coated, together with the mixture in which they are packed, are heated in a closed vessel to between 1825 and 2375 F. The action of the aluminum and the chloride results in an alloy between the liberated chromium and the iron. The depth of penetration depends on the percentage of metal oxides and the time at the working temperature.

Application. Chromizing has been used to protect turbine buckets against corrosion and erosion. Containers used for copper brazing tungsten contacts have been chromized so that the copper would not braze the contacts to the container. The hydrogen atmosphere used for copper brazing usually contains enough water vapor and oxygen to oxidize the chromium on the surface, thus preventing the copper from wetting it.

Any steel parts that must withstand atmospheric corrosion or the attack of nitric acid, can be chromized to give satisfactory resistance. The chromized surface layer is virtually free from carbon, and no attack occurs as a result of carbide precipitation.

Lead Coatings on Steel

By J. L. Bray*

LEAD has excellent resistance to atmospheric corrosion as compared with iron or zinc, because of its less negative electrode potential as well as the formation of a relatively continuous and adherent protective film over the surface. Lead deforms easily under applied force, and the low temperature of recrystallization permits lead to conform to movements in a steel base with a minimum of disruption. The melting point of lead is relatively low, and consequently few operational difficulties are encountered in hot dipping. At temperatures slightly above the melting point (621 F) lead is quite fluid, easily handled, and its vapor pressure is very low. Lead always costs much less than tin and usually somewhat less than zinc. (In 1939 lead sold at 5.05 cents per lb, zinc at 5.51, and tin at 50.3.) The losses of lead from oxidation and drossing, are less than the corresponding losses of zinc; less time is consumed in cleaning the bath, and the life of the equipment is lengthened considerably by reason of the lower operating temperature and the lower solubility of iron in lead. Lead-coated sheets solder easily and rapidly, consuming less solder than uncoated sheets. The lead also serves as an effective lubricant in forming, stamping and spinning.

Operating against these advantages are some very serious disadvantages. (1) Lead does not form intermetallic compounds or solid solutions with iron and consequently, when pure lead is used as a coating medium, the bond is entirely mechanical with all the shortcomings of that type of bond. For this reason pure lead is seldom used for hot dipped coatings and is generally alloyed with other elements to form a bond with the steel. (2) Great care in manufacturing is necessary to minimize pinholes, which form readily when the molten coating solidifies and which become areas for accelerated corrosion. (3) Lead is relatively soft and its resistance to wear and abrasion is low. (4) Although lead is resistant to atmospheric corrosion, it readily forms an unsightly initial coating of oxide or sulfate, particularly when the lead contains impurities. It is noteworthy too that lead coatings may not provide as good protection in rural atmospheres, probably because of the absence of constituents that form sulfate. (5) The metal is commonly regarded as cathodic to iron, although the potential difference is not great, and corrosion will occur at the expense of the iron.

Lead Spraying. A metal surface may be coated with "atomized" lead or a lead alloy by means of a special spray gun. For details, see the article on "Sprayed Metal Coatings", page 720 in this Handbook.

Hot Dipping with Pure Lead. This requires very care-

* Head, School of Chemical and Metallurgical Engineering, Purdue University, Lafayette, Ind.

ful preparation of the steel base, the use of a closely controlled and relatively pure flux, and close regulation of dipping temperature and duration of immersion. Oil or grease may be removed by the conventional solvents or detergents. Then the steel is pickled (at 160 F) in a bath containing 6 to 12% sulfuric acid. The iron content of the bath should not exceed 5%. After pickling, the steel articles are treated for 10 to 15 min in a bath of 5 to 10% hydrochloric acid (at 120 to 150 F) containing an inhibitor (5% Fe max). The articles are then immersed in a solution of 1 part of zinc-ammonium chloride in six parts of water (8% Fe max). It is essential that the articles remain wet with this solution until they are dipped into the bath of molten lead.

The bath of commercially pure lead is maintained at a temperature of 690 to 710 F, and should be covered with a layer of molten flux, the preparation and composition of which are extremely important. The flux bath prepared from zinc-ammonium chloride should be about ⅛ in. deep. When operating best this bath has a dark color and gives off almost no fumes. Aside from additions to replace losses, the principal precaution is to ensure complete solution of the crystals and to confine flux additions to the entrance end of the bath.

Immersion in the flux bath for 10 to 20 sec is sufficient, but a much longer immersion, depending on the mass of the article, is required in the lead bath. When the coated article is withdrawn from the bath, the excess metal and flux are removed by shaking or centrifuging. Then the article is quenched in water, and in some instances, tumbled in sawdust to improve the appearance. Sheet metal workers often rub linseed oil and lampblack on freshly exposed lead installations to develop a more sightly appearance. A coating of pure lead may "crawl". This is particularly important in pipe linings where a correlation must be established between diameter of the pipe and thickness of the lining, because of the effect of increased arc.

The weight of the coating thus produced may be varied from 0.16 to 1.4 oz per sq ft. The thickness may be controlled by variations in the temperature of the bath, the length of immersion and the amount of shaking or centrifuging. This method should probably be used only with articles subject to a minimum of distortion, because the bond is altogether mechanical and might not serve in many applications of wire or sheet.

Low-Tin Alloy Coatings. Tin, as a constituent of the bath, is used as a binding agent with considerable success. The most satisfactory alloy has been one that contains not more than 2.5% Sn, nor more than 2% Sb, with the remainder lead. Antimony serves to harden the alloy and to reduce the amount of white corrosion product formed during weathering. One company uses an alloy containing 0.25 to 0.50% Ag also, and maintains that such an alloy has better bonding properties. Sheets to be coated are first pickled in sulfuric acid, with or without an inhibitor, are washed well to remove acid and iron salts, and then are stored under water in a storage bosh. The sheets pass from this tank through a pair of "squeegee" rolls into a preflux tank, then through an anhydrous flux on top of the molten alloy bath, and finally into an alloy-coating machine similar to that employed in the conventional process for galvanizing sheet. After the sheets have passed down through a flux box into the alloy bath (held at a temperature of 630 to 650 F) they come out through a set of stripping rolls that serve to regulate the thickness of the coating. At present this thickness may be controlled between 0.4 and 1.1 oz per sq ft. (The nomenclature is the same as for galvanized sheets; that is, a 1.0-oz coating means 0.5 oz on each side of the sheet.) Still lighter coatings may be produced by "oil wiping" (passing the sheet through oil held at a temperature of about 600 F). When an asbestos or charcoal wipe is applied to wire, coatings as heavy as 1.25 oz per sq ft may be produced.

Another alloy that may be used for coating—especially on sheet and wire—contains about 0.55% Zn. Molten lead can hold only a small percentage of zinc in solution—approximately 2% or less, depending on the temperature. If the zinc content is too low, the adherence of the coating to the steel base will be imperfect, and if too high, the sheet may have a rough surface. Apparently the bond is a chemical one between the needles of zinc in the alloy and the steel sheet, through the medium of an intermetallic compound similar to that produced in galvanizing. One method uses a sheet with a very light coat of zinc as a base. Such a "tight" sheet may be passed down through a conventional flux in a galvanizing unit and coated with a layer of the alloy described above. Theoretically, this type of sheet has the superior corrosion resistance of lead, but is also reinforced by the zinc that remains underneath. However, after a prolonged exposure in a marine atmosphere, the lead coating may blister.

High-Tin Alloy Coatings. These are described in the article "Tinning of Steel", page 709 in this Handbook.

Applications of Dipped Coatings. Sheet and wire (a large tonnage is used as "terne" coating) coated with lead, can compete actively with galvanized articles wherever atmospheric corrosion alone is concerned, although such articles are ordinarily painted. If wear or abrasion is involved, lead is too soft to give satisfactory service. Many fabricated articles—for example, pole-line hardware—lend themselves to hand dipping, by reason of shape or use. Bolts, washers, nuts, plates, hooks and other fixtures used in industry, can be coated effectively, as well as gasoline tanks, barrels, cans, farm equipment, military equipment, air ducts and electrical hardware. Other ferrous alloys can be coated with lead after suitable preparation; for example, cast-iron objects, after they have been given a decarburizing treatment before fluxing and dipping.

Incidentally it has been found that paints adhere better to lead-coated sheets than to most metallic coatings and these sheets are more easily painted. Such articles as gutters, spandrels, flashing, and corrugated siding must frequently be decorated with color. Any of the standard lead pigments are suitable as priming coats for lead-coated sheets.

Lead Plating. The ductility of electrodeposited lead is greater than that of hot dipped coatings because of greater purity. However, lead is frequently deposited in the form of a loosely adherent, sometimes spongy metal, and is likely to contain pinholes. Lead cannot be deposited with the brilliant lustrous surface of nickel, cadmium or tin. More than ordinary care must be used in preparing the steel base for plating; if the steel surface is not clean, any attempt to plate it will result in failure. Lead is soft and easily worn; consequently, the common limits of coating thickness are rather high—0.003 to 0.005 in. Slight porosity may be overcome by light mechanical working of the coating.

Silicon Impregnation

By Harry K. Ihrig*

THE IMPREGNATION of iron and steel with silicon (siliconizing) to form a case that contains about 14% Si, greatly increases the resistance of the steel to corrosion, heat and wear.

Metals Treated. Wrought or cast low-carbon steel, low in sulfur, is best suited for impregnation with silicon. High-carbon low-sulfur steels can be treated satisfactorily, but impregnation is slower. For example, SAE 1045 steel requires about twice as long as low-carbon steel, for production of a specific depth of case. The silicon case on high-sulfur free-machining steels may be penetrated under corrosive conditions, with subsequent cracking and spalling of the case, resulting from attack on the underlying core.

White and malleable irons can be treated, but because of the high sulfur content, the resulting cases are ordinarily less satisfactory than those obtained on low-sulfur steel. Gray iron, because of high sulfur content and because of the tendency to "grow" at treating temperatures, does not usually form a satisfactory case.

Generally, alloy irons and steels, particularly those containing chromium, do not respond to treatment so well as do plain low-carbon steels.

Preparation of Metals to be Treated. The decarburized layer often found on forgings need not be removed. Sand embedded in castings must be removed by pickling or sand blasting. Though light mill scale is harmless, heavy annealing scale should be removed. Because the temperature for the treatment is above the transformation temperature range for irons and steels, it is advisable that all residual stress be removed before the impregnation process; otherwise, the stress will be relieved during the process and distortion may result.

Process. Essentially, the process consists in subjecting iron or steel to the action of silicon carbide and chlorine at a temperature of 1700 to 1850 F. Instead of silicon carbide, ferrosilicon or mixtures of ferrosilicon and silicon carbide may be used. Either a rotary or pot type of furnace is satisfactory. The chlorine is added after the parts have reached the desired temperature. Ordinary carburizing equipment is used with only slight modifications, and no inert or reducing gas is necessary during the silicon impregnation.

The exact nature of the reaction is not fully known. At temperatures up to 1850 F, it appears essential that the carbide be in contact with the article to be treated. It is probable that chlorine liberates nascent silicon from the silicon carbide, and this diffuses immediately into the metal under treatment.

The case may be of any desired depth from 0.005 to 0.100 in. A case from 0.025 to 0.030 in. deep is usually produced on low-carbon steel in two hours. Ordinary chlorine gas of about 99% purity is used. The amount of chlorine needed depends on the size of the charge to be treated and the thickness of the case desired. The amount is determined experimentally for a specific job and then held constant for the particular charge.

Structure and Composition of the Silicon Case. Iron can hold approximately 15% Si in solid solution.[4] In a determination of the composition of the case, analyses were made of successive surface slices (0.01 in.) of the case on a low-carbon steel (0.12% C, 0.14% Si, 0.52% Mn, 0.026% S). The results showed the silicon content of the outer portion of the case (approximately two-thirds or 0.040 in.) to be substantially constant (14.02 to 13.54%, avg 13.85%) and to decrease within the remaining portion (approximately one-third or 0.020 in.) to 5.4%. The uniformity in silicon content of the outer part of the case makes it possible to grind such a case to a considerable depth without damaging it. The outer silicon-rich portion consists of a single microstructural constituent—a solid solution. The second (carbon-bearing) constituent first appears with the marked decrease in silicon content. A structural peculiarity is the higher concentration of the carbon-bearing constituent immediately below the higher-silicon layer, which suggests forced migration of carbon ahead of the silicon that is diffusing inwardly.

* Director of Laboratories, Globe Steel Tubes Co., Milwaukee

Mechanical Properties. Siliconized articles show a case hardness of Rockwell B 80 to 85. Although not file hard, such parts cannot be machined or cut with a hacksaw by ordinary means.

Standard tension-test pieces cut from the same bar of SAE 1015 steel showed the following results before and after impregnation with silicon:

Property	Untreated	Treated
Elastic limit, psi	37,750	37,900
Ultimate strength, psi	60,550	51,400
Elongation in 2 in., %	38.5	19.5
Case cracked at psi	.....	41,600

The case did not crack until the steel had been stressed beyond the elastic limit. After the case had cracked, the cross section was reduced and thus the tensile strength was lowered. Although the ductility of the case is not so high as that of the core, treated tubes are ductile enough to withstand being rolled into headers. The case will not spall off under vigorous hammering. However, sharp corners should be rounded off to provide support by the core for all portions of the case.

Impregnation with silicon destroys the effect of all previous heat treatment. The case cannot be changed by any known heat treatment, but the core of a siliconized steel may be heat treated to obtain any properties possible with the type of base metal used.

Resistance to Corrosion. Articles impregnated with silicon are resistant to nitric, sulfuric, and hydrochloric acids, with decreasing resistance in the order named.

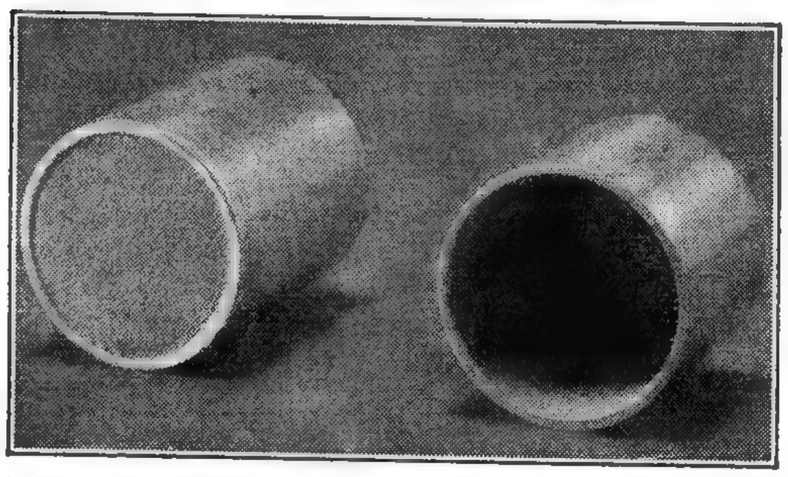

Fig. 1 Bar with silicon case, cut in half, one surface (*left*) lightly etched and the other (*right*) boiled in dilute nitric acid, leaving only the corrosion-resistant shell

Figure 1 shows two portions of a treated bar, one of which was boiled in dilute nitric acid to dissolve the core; only the case was left. The other half was etched lightly to show the case.

In 10% boiling sulfuric acid, a ½ by 2-in. siliconized round showed the following losses in weight in successive 24-hr periods:

Period	1st	2nd	3rd	4th	5th	6th	7th	8th	9th	10th
Loss, %	3.1	0.5	0.3	0.4	0.4	0.2	0.7	0.7	0.7	0.3

Characteristic of high-silicon alloys, the attack in the first 24 hr was relatively high, but after that it decreased greatly. A companion specimen of carbon steel under the same conditions was entirely dissolved in about 18 hr, and one of 18-8 Cr-Ni stainless steel in 24 to 30 hr.

Articles that have silicon cases are not recommended for use in boiling mineral acids, because after the case has been perforated the core is rapidly attacked.

Resistance to Heat. The silicon case is resistant to scaling up to 1800 F. At this temperature excessive grain growth occurs in the steel core and the case may crack, but temperatures of 1200 to 1600 F permit long life.

Resistance to Wear. Under conditions of frictional wear, such as those to which shafts and cylinder liners are subjected, the siliconized case has stood up well and the surface is virtually nongalling. Parts that have silicon cases wear well against each other. Where conditions of corrosion and wear exist together, the silicon case is especially effective.

If, after finish grinding, a part that has been treated with silicon is heated to 250 to 300 F in a heavy oil, some of this oil is absorbed, and thus the treated part functions as a self-lubricating bearing. This property of absorbing oil is especially effective where outside lubrication is impossible. Amsler wear tests have shown a fivefold improvement in resistance to wear of an oil-treated, siliconized part, as compared with a plain siliconized companion specimen.

The reason for the oil absorption is not certain; a plausible explanation is that the case contains graphitic spots or voids left by graphite, which retain the oil.

The silicon case is not recommended for high-velocity abrasion, such as exists in sandblasting.

Distortion. A slight expansion that has not been adequately explained, occurs during the treatment of steel parts. This varies with the type of alloy being treated. Parts actually lose in weight during treatment because the heavier iron has been replaced by the lighter silicon. The following table illustrates the changes in dimensions and weight before and after treating an SAE 1020 steel bar, 1 in. in diam.

Property	Before Treatment	After Treatment
Weight, grams	602	571.4
Diameter, inches	1.000	1.003
Length, inches	5.985	5.989

Because parts are not quenched after the silicon impregnation, only slight distortion occurs. Where the type of part permits, it may be straightened cold a few thousandths of an inch, or considerably more if heated to a temperature of about 1200 F.

Applications. The following are some of the applications in which siliconized parts made from ferrous metals have given satisfactory service when subjected to corrosion, heat, or wear: automotive water-pump shafts, rocker arms, cylinder liners, and valve guides; valves, fittings and similar parts for the chemical, paper, and oil industries. Also forgings, steel and malleable iron castings, thermocouple tubes, nails, screws, bolts, and tubing are siliconized where corrosion, heat, or wear are problems.

Tinning of Steel

By Robert J. Nekervis* and Bruce W. Gonser*

THE IMPORTANCE of the tin plate industry in the United States is indicated by the 1945 production of 2,836,339 tons. Hot dipped tin plate accounted for 70% of this total and electrotin plate for 30%. Containers and closures use about 95% of the tin and short terne plate consumed in this country. Packers cans (and closures) and general line cans are the two large divisions in container manufacture.

The steel base for these containers is usually furnished in six temper classifications; the stiffness increases from Temper 1 to Temper 6 (T1 to T6). Tin plates that have the characteristics of T1 and T2 are used in deeply drawn containers. Plates of T3 and T4 are commonly used for ends and bodies of cans for processed food. The T5 plate is used where higher resistance to buckling or paneling is required. T6 is used for the ends of cans that are subject to exceptionally high internal pressures. The carbon, manganese, and sulfur contents of the steel base will usually be within the following ranges, depending on the temper: 0.04 to 0.11% C, 0.25 to 0.53% Mn, 0.03 to 0.05% S max. Apparently these compositions have no critical influence on the resistance to corrosion of cans for processed food, whereas the influence of phosphorus, silicon, and the heavy residual metals affects the resistance to some products. The composition of the steel base is controlled to obtain the proper balance of strength and resistance to corrosion for individual applications. Necessary stiffness is obtained by the control of both the extension of the sheet (temper rolling) and the metalloid content of the steel. The low-metalloid steel used for many corrosive foods is known as Type L. This steel is produced in the lower tempers; the stiffness is controlled by the amount of extension received during temper rolling. The higher tempers (that is, the stiffer base plates) are known as Type MC plates, and the stiffness is obtained largely through control of the metalloid content. This type is suitable for mildly corrosive and noncorrosive food products.

Other classifications, such as nonaging aluminum-killed steels, are produced, but are for special uses and are too numerous to include here. In the United States, all the thin sheets for tin plate and terne plate are cold reduced; the last hot pack mill for the production of tin plate was closed in August 1943.

Details concerning the cold reduction of sheet to the thickness used for tin plate may be found on page 352. The thickness, or gage, of tin plate is measured in terms of pounds per base box, a unit peculiar to the tin industry. A base box corresponds to an area of sheet of 31,360 sq in. (217.78 sq ft) of any gage, and is applied to tin plate weighing from 55 to 275 lb per base box. For conversion to the approximate thickness in inches, the basis weight is multiplied by 1.1 and divided by 10,000. For example:

$$107 \text{ lb per base box} = \frac{107 \times 1.1}{10{,}000} = 0.0118 \text{ in.}$$

The amount of the tin coating on tin plate is expressed also in pounds per base box. Amounts of most terne coatings are expressed in pounds per double base box, which is equal to twice the area of the standard base box for tin plate. However, for light terne plate that is made with the same equipment as tin plate and used instead of tin plate for containers, the amount of coating is ordinarily expressed in pounds per single base box.

The Manufacture of Hot Dipped Tin Plate and Terne Plate. After the temper pass, in one operation on a shear line, the coils are uncoiled, trimmed, sheared to size, leveled or flattened, and sorted into piles of sheet that are within gage limits and free from pinholes. The sheets are then "white pickled" in three successive tanks, the first two of which contain 3 to 6% sulfuric acid at about 160 F. The final tank is for rinsing. After being rinsed, the plates are stored in boshes that contain slightly acidulated water.

Hot Dip Tinning. With the exception of a small amount of plate coated more heavily than is usual, steel sheet is tinned in automatic machines. These machines feed the base plate through a flux of zinc chloride into a tin bath and up through a compartment containing palm oil, where excess tin is removed. Auxiliary equipment carries the sheet through suitable cleaning attachments, where part

* Battelle Memorial Institute, Columbus, Ohio

or almost all of the adhering palm oil is removed and the plate is polished. The steel sheets are conveyed through the tin and palm-oil compartments by means of pairs of steel rolls, one pair in the tin compartment and three pairs in the palm-oil compartment, one above another, to squeeze off the excess of molten tin. The rolls in the palm-oil compartment have fixed scrapers of asbestos or soapstone, which aid in removing tin and tin-iron "scruff" that adhere to the rolls after contact with the tin plate. The rolls in the palm-oil bath are held against the sheets by slight spring pressure. The pot and rolls of the tinning machine are designed so that two or three sheets can be tinned, side by side, at the same time. The tin bath, containing 5 to 7 tons of first-quality tin, is usually heated near the entrance end by immersed gas-heaters.

Palm oil acts as a flux to aid in obtaining good distribution of tin, and serves as a cooling and protective medium so that the emerging tin will freeze quickly without oxidizing. The temperature of the palm oil at the top of the bath is kept as low as possible by recirculation; this temperature is preferably 460 to 470 F. At higher temperatures, the palm oil polymerizes readily, which may cause yellow streaks in the tin plate. In a typical individual circulating system, each pot holds about 475 gal of oil with an additional 125 gal in a water-jacketed reservoir, which is replenished daily. When the Saybolt viscosity of the oil reaches 100 to 108 at 210 F, the reservoir is drained and refilled with new oil. This cycle takes about two weeks. For starting a tin pot, some used oil is always mixed with the new oil, so that the Saybolt viscosity is at least 80 at 210 F. Sumatra palm oil is generally considered to be the best for use in tinning, because it is of more nearly uniform quality and contains a maximum of 5 or 6% fatty acid, compared with perhaps double this amount in African palm oil.

Steel sheets are passed through the tin pot at the rate of 25 to 30 fpm. The temperature of the bath may vary from about 575 to 650 F at the entrance end of the bath, according to the tinning speed, and may be 100 F lower near the palm-oil compartment. Some tin is lost in dross and in concentrations of tin along the edges, particularly at the bottom or "list" edge of each sheet; hence the yield, as calculated from the tin on the finished sheets near the center, is only 85 to 90% of the tin consumed. Thus, an average coating of 1.10 lb per base box of tin, as measured by the consumer, may mean a calculated coating or "tin yield" of 1.25 lb, based on the tin consumed in the mill.

Palm oil is removed from a finished plate by the use of an alkaline cleaner, by absorption in a dry material, such as bran, or by a combination of the two. Dry flannel rolls may be used for final cleaning. When the plate is to be lithographed or enameled, it is desirable that virtually all the oil be removed; for other uses, a residual film of oil may be desirable to preserve the finish or to act as a lubricant during stamping operations.

Grading of Tin Plate. After being coated, every sheet of tin plate is inspected and is either classified as "unassorted" (meaning that one lot contains both "primes" and "seconds") or is separated into four grades as follows:

"Primes" are tin plates that are free from defects readily observed by the unaided eye.

"Seconds" is the designation given to tin plate that has imperfections in moderate degree or extent, which may be classed in three general groups—imperfections in the coating, imperfections in the base material, or other manufacturing defects.

"Menders" are plates having a defect that may be eliminated by passing the plate through the tinning unit a second time.

"Waste sheets" are sheets that have prohibitive defects, for example, seams and buckled plates. Such plates are detinned and the base plate is returned to the steel plant as scrap.

The proportion of prime sheets varies from time to time, but usually is approximately 85% of the total, with seconds and menders about 15% and about 2% waste.

Terms Indicating Thickness of Coatings. Sheets that have the standard thicknesses of coating are known as "cokes", and those with heavier coatings are "charcoals" (Table I).

Because the supply of tin in the United States was seriously curtailed during World War II, the WPB imposed a maximum tin yield of 1.25 lb per base box on hot dipped plate lighter than 112 lb per base box in thickness.

The production of charcoal plates, a very small percentage of the total tin plate, usually requires special equipment. Sometimes heavy coatings are produced by first tinning the sheets in a tin pot used for dipping coke plates, then dipping them in a second pot at a relatively low temperature, and finally dipping them in palm oil. In other instances, an entirely separate unit is used. Charcoal plates may carry as heavy a coating as 14 lb per base box, but for most uses, the coating is from 2 to 7 lb per base box.

Table I. Weights of Coating on Hot Dipped Tin Plate

Class		Minimum Average Weight of Coating, lb per base box (Fed. Spec. U. S. 1936)
Standard Coke Plate		Not specified
Best Coke Plate		1.19
Kanner's Special		1.40
Charcoal	1A	1.80
	2A	2.30
	3A	2.80
	4A	3.50
	5A	4.20
Premier		4.90

Testing Tin Plate. Since virtually all hot dipped tin plate is used in making cans, or closures for cans and bottles, the resistance to corrosion is an important property, and is frequently tested at the tin mill as well as by the fabricator. Actual records of performance provide the most reliable information. Accelerated tests are made by holding the packed container at an elevated temperature. In an even more accelerated test that has been used rather widely, the time is measured for a definite amount of hydrogen to be evolved when the tin plate is immersed in warm dilute hydrochloric acid, under standardized conditions.

Terne Plate. The sheet steel for terne plate is prepared in the same way as for making tin plate. Likewise, much of the thinly coated terne plate ("manufacturing ternes") is made in the same way and with the same machinery. The only difference is that a terne metal bath consists of an alloy of tin and lead, and the temperature of the bath and oil is somewhat higher. Spent palm oil from the tin pots is commonly used for draining. Hydrogenated fish oils also are used to some extent. Ternes so made contain only 15 to 25% Sn, and the coating thickness for most applications—for instance, for lubricating-oil cans—is only about 0.00005 in. The WPB (M43, March 8, 1945) defined terne plate made with tin-mill equipment as "short ternes", and limited the pot yield to 1.30 lb per base box.

Common "roofing tin" is heavily coated, hand-dipped terne plate, which is usually designated as "short terne" to differentiate it from the "long terne" or larger sheets. The composition of the base plate is usually selected with some regard for resistance to atmospheric corrosion, and is frequently machine-coated with the terne mixture as part of the preparation for hand dipping. For roofing, a 25% Sn–75% Pb bath is commonly used. Sheets are dipped singly in one or two terne baths, then into palm oil. The coatings are designated in terms of pounds per double base box. The range of coatings varies from 12 to 40 lb on this basis. The size of the spangle or mottle gives some indication of the thickness of coating. The size of mottle decreases with an increase in coating thickness if the conditions of manufacture are similar. However, the size of mottle may be varied by changing the rate of cooling.

Long ternes, machine-coated sheets that are comparatively large, are usually made in galvanizing shops rather than tin mills, and are similar to galvanized sheets in size. As with thinly coated terne plate, the base metal is passed through a zinc chloride or zinc-ammonium chloride flux, through a terne metal bath, and through a palm oil finishing compartment, by machine. The coating obtained is normally 8 lb or less per double base box. The WPB

(M43, March 8, 1945) defined long ternes as terne coated in sheet-mill coating machines, and restricted the pot yield to 4 lb per base box and the tin content to 10% max. Hot dipped terne coatings have been applied continuously to coils of 24-gage and 26-gage sheet commercially.

Terne metal is more expensive than zinc, but much cheaper than tin. The advantage of terne lies in the fact that it has certain of the properties of tin at a much lower cost. Under alternating exposure to air, terne metal will remain bright where zinc will form oxides and carbonates. Therefore, terne plate is used for gasoline tanks, where any products of oxidation might clog the fuel line. The surface of terne plate is soft and has a greasy feel. The metal will not flake off, is very ductile, and is much used for deep drawing operations where a corrosion-resistant material is desired. A further advantage lies in the fact that it can be painted without weathering, which makes it a useful roofing material.

Tinning of Wire and Narrow Strip. Wire and narrow strip are hot tinned continuously. The excess of tin is removed by running the wire or strip through a wiping fixture, which is packed with asbestos, or through charcoal or, for wire, through a tungsten carbide die. This gives a thin coating, usually less than 0.00005 in. thick or amounting to about 0.025 to 0.035 oz per sq ft of single surface. (Strip of this weight would be doubled to give weight per square foot of material, or the equivalent of 0.6 to 0.9 lb per base box of tin plate.) For heavier coatings, other means of wiping have been suggested and used to a limited extent; for example, steam jets, compressed air, and a strong countercurrent flow of palm oil.

Preparation consists essentially of cleaning or pickling and passing the wire or strip through a zinc chloride flux before it enters the pure tin bath. Since no palm oil is used, the surface of the tin bath should be covered with charcoal to avoid oxidation. Strip wider than 6 in. is seldom tinned continuously in this way.

Tinning of Fabricated Articles. Before tinning, fabricated articles are degreased by vapor cleaning or other suitable methods. This operation is followed by pickling, as in hot dilute sulfuric acid; by temporary storage in dilute hydrochloric acid, as in making tin plate; and finally by fluxing and tinning.

Zinc chloride, or zinc chloride containing a small amount of ammonium chloride, is a positive flux widely used in tinning fabricated articles. Molten tallow is sometimes used for fluxing. Usually the products to be tinned are first immersed in a preliminary tinning bath and then immersed in a second tinning pot to secure a better coating. In this way much of the iron-tin dross remains in the first pot, and the second pot can be maintained with a purer tin bath. To ensure complete coverage, the articles may be brushed or wiped while the tin coating is still fluid and then redipped momentarily to leave a free, smooth surface. As a final operation, the articles are either withdrawn through a palm-oil or molten-tallow division of the final tinning pot, or are dipped in a separate bath of such material to permit drainage of the tin coating. The amount of tin adhering depends largely on the temperature of this finishing bath and on the time permitted for drainage, but the coating is always heavy in comparison with that on standard coke tin plate. As a final step, the edge or bottom portion of the article, to which excess tin has drained, is usually dipped into a hot tin bath to remove the heavy tin concentration. Cloth, bran or sawdust may be used for the final polishing and removal of grease.

Tinning of Cast Iron. Cast-iron parts are not readily tinned, because of the graphite in the iron and the difficulty in pickling to give a clean surface. Where possible, it is best to use sandblasting or other mechanical means to remove the casting skin effectively. This treatment is followed by pickling in warm sulfuric acid (5 or 6%) containing an inhibitor, storage in dilute hydrochloric acid, fluxing in zinc chloride containing up to 35% ammonium chloride, and tinning in the general manner described for fabricated articles. Frequently, pickling in cold 5% hydrofluoric acid is necessary in order to remove residual sand. Surface decarburization does not always help to make the casting more easily tinned, but it is advantageous to have an intermediate layer of pure iron, copper, or nickel, which may be plated on electrolytically or by replacement.

A marked departure from the traditional procedure in preparation for tinning, is the immersion of castings in a salt bath immediately after sandblasting.

Electrotin Plating. Two advantages of electrotin plating —the possibility of tinning in continuous lengths and of regulating the coating to any desired thickness—led to large-scale experiments before 1942. The need for strict economy in the use of tin during the three years thereafter, resulted in the construction of 28 electrolytic tinning lines in the United States. These have been used largely to give coatings of 0.25 to 0.75 lb per base box, or thinner than it is possible to obtain by hot dipping.

Plating Baths. The types of electrolytes used in tin plating are of two broad classes—those using an acid electrolyte and those using an alkaline electrolyte. Satisfactory tin plate can be made from either type. Each has certain advantages, and the choice of bath is governed by plant considerations and administrative aspects, such as patent rights.

The alkaline baths consist essentially of either sodium stannate and caustic soda, or potassium stannate and potassium hydroxide electrolytes. Buffer salts (acetates) and agents to oxidize traces of stannites, may also be added. The current density of the sodium stannate baths is approximately 20 to 30 amp per sq ft; the temperature is 180 to 190 F. Anode and cathode current efficiencies range from 60 to 80%.

Greatly increased plating (cathode) current densities are possible (up to about 200 amp per sq ft) if potassium stannate and hydroxide are substituted for the sodium salts. However, higher anode current densities are not possible in present practice without greatly reduced current efficiency. The anode current density thus limits the use of this process.

The acid bath consists essentially of stannous sulfate and an aromatic sulfonic acid with addition agents. The bath depends on the use of colloidal addition agents for successful operation.

Possible current densities with various types of baths vary from 10 to 400 amp per sq ft. The temperature of the bath ranges from 70 to 100 F. Cathode and anode current efficiencies are nearly 100%.

Halogen electrotin plating solutions are being used by two major producers of tin plate. The principal constituents of the solutions are tin chlorides and fluorides with an organic addition agent. The tin content may be varied from 15 to 40 g per liter, depending on current density and the speed of the strip. The total organic addition agent is about 2 g per liter. The bath is operated at a pH of 2.7 with an optimum temperature of 150 F. Current density in actual operation is 185 amp per sq ft. With various compositions of the solution, a range of current densities from 50 to 500 amp per sq ft is possible. Cathode and anode efficiencies are reported to be 97 and 100%, respectively.

Basic Design of Lines for Electrolytic Tinning. In typical practice, the sheet is received directly from the temper mills in coils. These coils are tinned in one of three basic types of lines: the vertical tank line for use at constant plating speed; the vertical tank line for use at variable plating speed; and the horizontal tank line for use at variable plating speed.

In the sequence of operations on these lines, the strip is uncoiled and the ends are welded together, either at lower line speeds or with provisions for feeding strip to the plating tank at an unchanged rate, by means of a looping device. The strip is usually free from grease so an electrocleaning step may be omitted. Pickling follows, either in a regular acid pickle or in an electrolytic pickle; then the strip is scrubbed or washed and passed into the plating tank. The strip may be passed through the line either in a vertical serpentine manner or horizontally. If passed horizontally, the two sides of the strip are plated separately. Most plants filter the electrolyte continuously. After leaving the plating tank, the strip is washed, dried, and flow-brightened, that is, the electrodeposited tin coating ■ momentarily melted and is then quenched im-

mediately. Fusion is accomplished in many ways—by induction heating, resistance heating, between radiant tubes or banks of ceramic radiant heat burners, or by melting in heated oil. All such methods can be used at high speeds.

Sometimes the brightened strip is passed through a chromate solution, where it is treated chemically to provide an invisible oxide film. Then after the strip has been rinsed in water and dried, a thin film of oil is imparted to the surfaces by one of several methods—branner oiling, emulsion oiling, spraying, or vapor condensation. From this point, the strip is sheared in tandem with the electroplating line or as a separate operation, if the speed of the plating line exceeds 600 fpm, the maximum shearing speed. Plating line speeds vary from about 500 to 1000 fpm. The higher-speed lines have been operated as rapidly as 1350 fpm.

Zinc Coatings

By W. M. Peirce*

ZINC COATING, or "galvanizing" as it is commonly termed, is a very old method of protecting iron and steel against corrosion. It is applied to a greater tonnage of steel products than any other method of metallic coating and provides the most economical protection for products of the type to which it is properly applicable. The major established applications of zinc coating on steel products include roofing and siding sheets, wire and wire products for all outdoor exposure, articles fabricated from sheet steel such as range boilers, pails, cans and tanks, hardware for outdoor use, pipe and conduit, and exposed structural steel. Nails are galvanized not only to extend the life of the nail but also to prevent rotting of the wood, which occurs around rusted nails. In short, wherever steel is exposed to atmospheric corrosion, zinc coating is a standard and effective method of protection.

The usefulness of zinc coatings depends, first, on the relatively slow rate of corrosion of zinc as compared with that of iron, and the much less objectionable appearance of the white, nonstaining corrosion products of zinc as compared with iron rust; and, second, on the electrolytic protection afforded to iron by zinc. This electrolytic protection prevents iron from corroding at minor discontinuities in the zinc coating, such as sheared edges of sheets, cut ends of wire, or abrasions in the surface. This electrolytic or "sacrificial" protection extends away from the zinc coating over exposed iron surfaces for a sufficient distance to protect the steel at cut edges, scratches and other discontinuities in the coating. The distance varies with the properties of the film of moisture as an electrolyte, and is a maximum under such conditions as the presence of salt water.

Zinc coatings have the longest life under conditions of rural exposure where the air is free from sulfur gases and other industrial fumes. They give satisfactory service in salt air, also. They are more rapidly attacked in highly acid industrial atmospheres, but nevertheless are widely used in such atmospheres because no more effective and economical method of protection has yet been found. Frequently the combination of a zinc coating and an acid-resisting paint or other organic coating is most effective. The zinc forms a more durable base for the organic coating and prevents rapid failure by undercutting corrosion when the organic coating is penetrated.

When zinc coatings are to be painted for decoration or protection, it is desirable to use a suitable primer, such as a zinc dust primer that ages without serious loss in adherence. The adherence of ordinary paints is improved by weathering of the zinc surface or by chemical etching. The best adherence is obtained by the use of phosphate-treated galvanized sheets to which even ordinary paint adheres well.

Zinc coatings are occasionally subject to an abnormal type of corrosion that results in bulky white corrosion products. Such corrosion originates from contact with water without free access of air. Galvanized sheets should be stacked on edge rather than flat, to prevent rain or condensed moisture from being held between them, which can cause this type of corrosion. Zinc-coated material to be used where "sweating" or other exposure to stagnant water may occur, can be protected by a chromate surface treatment that has been developed for this purpose.

Since zinc has an appreciable rate of corrosion under the conditions of exposure where zinc coatings are used, and since the coatings that can be applied readily are measured in thousandths of an inch or less, it is obvious that the life of the coating will not be indefinite but will be determined by the thickness of the coating. Many comprehensive researches have shown that all other factors—such as the method of applying the zinc coating, the purity of the zinc, and the extent to which it is alloyed with the iron—are minor in determining life, as compared with the thickness of the coating.

Occasionally, zinc coatings on steel are specified in terms of thickness in thousandths of an inch, or in terms of the weight of coating expressed as a percentage of the weight of the steel base. As a rule, however, zinc coatings are measured in ounces per square foot of surface for most products except sheet. The weight of coating on sheet is stated in ounces per square foot of sheet. Since the sheet is coated on both sides, this weight is twice the average weight of coating per square foot of surface. The terms "Regular", "Tight Coat", and "Extra Tight Coat", as used in the trade, refer to relative freedom from visible flaking of the coating when bent. Since this "tightness" of the coating to the base is ordinarily achieved by reducing the weight of coating, the terms have come to connote varying weights of coating. The "Extra Tight Coat" corresponds to the thinnest coating. Weights of coating for many classes of galvanized products have been specified by the ASTM and are given in Tables I and II. The ASTM specifications should be consulted for a description of the methods of measuring properly the thickness of coating (which varies in uniformity according to the method of application).

It should be noted that an unusual system of terminology is used in the wire specification; Class 1 or Class A is the lowest grade material and Class 3 or Class C is the best in every instance.

Tables I and II do not represent the maximum weight of coating desirable for every application nor the maximum obtainable.

Zinc coatings are applied commercially by four methods. The oldest and most widely used is hot dipping. In this process the steel is first pickled in sulfuric or hydrochloric acid to remove all scale, then washed to remove iron salts and finely divided iron. To be completely effective, this washing must be combined with scrubbing.

* Assistant to General Manager, Technical Department, The New Jersey Zinc Company (of Pa.), Palmerton, Pa.

Any iron salt or finely divided iron that is left on the surface, forms dross in the galvanizing pot. The steel is next "fluxed" in weak hydrochloric acid or in a strong zinc chloride solution, partially dried and introduced into a bath of molten zinc. Fluxes — usually ammonium zinc chloride mixtures — and various mechanical devices are used to keep the surface of the zinc bath clean at the points of entry and exit. These vary, of course, with the type of material being handled. Sheets are fed by driven rolls immersed in the bath, and come out between partially submerged grooved rolls. Wire is pulled through guides and emerges through sand, charcoal or a wad of asbestos held mechanically in contact with it. These exit rolls and "wipes" smooth the surface and remove some of the zinc. Products other than sheet and wire are handled semi-mechanically or by hand and may be shaken, jarred, rotated or centrifuged (as, for example, nails and small parts), to distribute the coating evenly and remove excess zinc. In all cases the work pieces must be handled properly until the coating has frozen, in order to avoid marking and to secure as even a distribution as possible. The appearance may be controlled by the use of cooling air, by the application of SO_2 or ammonium chloride to the still molten coating, and by local chilling to start crystallization and control spangle pattern.

Table I. Nominal Weights of Coating for Sheet According to ASTM Specification A 93–46

(Weight of coating on two sides expressed in ounces per square foot of sheet)

Ordered Coating Weights and Minimum Coating Limits	Minimum Coating — By Sheet Test	By Diagonal Triple-Spot Test	By Single-Spot Test	Practicable Limits of Galvanized Sheet, gage
2.75	2.50	2.35	2.00	No. 8 to 24
2.50	2.25	2.10	1.80	No. 8 to 26
2.25	2.00	1.85	1.60	No. 8 to 28
2.00	1.75	1.65	1.40	No. 11 to 28
1.75	1.50	1.40	1.20	No. 14 to 28
1.50	1.25	1.15	1.00	No. 16 to 30
1.25	1.00	0.90	0.80	No. 18 to 30

Variations of every step described above have been proposed and many are in use. For example, cleaning may be accomplished by oxidation and reduction of the surface. Fluxes can be eliminated if the material, with the surface free from oxide, is introduced through an inert or reducing atmosphere. The character of the alloy layers (*see* below) and of the coating may be varied by varying the composition of the steel surface—for instance, through control of silicon, carburizing, and phosphorizing—or by the addition of alloying elements to the zinc bath. Tin and aluminum, discussed later, are frequently used in this way.

The zinc bath for hot dipping is contained in a melting pot of suitable dimensions, fabricated from mild steel plates and heated, usually from the sides, by a uniform and carefully controlled source of heat, such as gas or electricity. If the temperature of the zinc is kept below 490 C and local overheating of the pot is avoided, the rate of solution of the iron pot in the zinc is very slow. The rolls and other machinery for handling the sheets or other materials through the bath, are also made of iron or steel.

In recent years an important development in sheet galvanizing has been made possible by the advent of the continuous sheet mill. Many of the problems of sheet galvanizing are connected with the entrance of a new sheet into the bath. The ends of single sheets must be trimmed after galvanizing, to remove irregularities and imperfections. The feeding of a continuous coil to the galvanizing pot overcomes operating problems and eliminates scrap losses from trimming. Methods of cleaning, annealing and after-treatment that are impractical with single short sheets, become practical and are used commercially with continuous sheet. Thus all steps of the hot galvanizing process for sheet are undergoing an important evolution (1947).

At this point, attention may be directed to the increasing production of flat wire and narrow strip in the field intermediate between wire and continuous sheet.

Table II. Minimum Weights of Coating for Wire According to ASTM Specifications

(Weight of coating in ounces per square foot of surface)

In the hot dip method the zinc alloys with the iron, forming one or sometimes two layers of definite iron-zinc alloys between the steel base and the outer layer of substantially pure zinc. The character and thickness of these alloys depend on many factors in the process: the temperature of the zinc bath, the duration of immersion, the composition of the steel and the condition of the surface. The adherence of the coating when bent is affected by the alloy layers; a thin, even layer of alloy is most desirable. During the last ten years more attention has been given to the influence of the steel base itself, and there is no doubt that important improvements in final quality have been made in some cases by attention to the type and quality of steel and the proper adaptation of the several steps in the hot galvanizing process to the type of steel used.

Hot dip coatings that consist entirely of iron-zinc alloys, are produced on sheet and wire either by very tight "wiping" of the steel (*see below*) or by subsequent heat treatment, which causes all of the zinc to alloy with the iron. Such coatings, when bent, crack in an infinite number of fine cracks with some dusting of the coating. The resulting appearance of the bend is more desirable than the flaking that sometimes occurs when ordinary heavy coatings are bent; but unless the flaking is very severe, the life remains proportional to the thickness of the original coating, regardless of flaking or bending, because of the electrolytic nature of the protection.

The purity of the zinc used in hot galvanizing, has an effect on the bending properties of the coatings. Of the common impurities found in zinc, cadium alone seems to be important. Its presence affects the bending properties of the coatings adversely by embrittling the outer layer of zinc. Aside from this, the grade of zinc used has no known effect on the properties of the coating. Because of the greater ease of obtaining heavy coatings with good bending properties when high-purity zinc is selected, this grade has been used for many years in producing high-quality galvanized wire, where the coating must be heavy and must not flake when bent as, for

example, in splicing. Attempts to use high-purity zinc for sheet galvanizing have not met with great success in operations with single short sheets, primarily because the flux on a zinc bath that is free from lead and cadmium lacks the fluidity of a flux on a bath containing a few tenths per cent of cadmium and from a few tenths to one per cent of lead (the amount found in the commercial grades commonly used). This lack of fluidity accentuates the operating difficulties and results in defects originating with the entrance of a new sheet into the bath. The advent of continuous sheet galvanizing has opened up the possibility of using high-purity zinc for sheet with the same success as on wire.

Tin, to the extent of 1 or 2%, is frequently added in the galvanizing of sheet and hardware, to control the spangle—that is, the crystalline appearance of the surface. To improve the brightness of the finish, aluminum also is added in very small fractions of a per cent, in the "hand dip" galvanizing of material other than sheet and wire. Aluminum has another very important effect when added in amounts of about two tenths per cent or higher. In such concentrations, it largely inhibits the formation of alloy layer, and thus improves the bending properties. In the ordinary sheet or galvanizing processes where chloride fluxes must be maintained, the presence of aluminum in such amounts ruins the flux. In a continuous sheet or wire, however, the steel can be cleaned and introduced into the zinc bath through an inert or reducing atmosphere instead of through flux. This makes it possible to take advantage of the desirable effects of aluminum.

The thickness of the coating applied by hot dipping depends on the duration of immersion (which controls the thickness of alloy), the speed of withdrawal from the bath (which controls the amount of zinc adhering), the temperature of the bath (which affects both), and the amount of zinc removed by wiping, jarring, or centrifuging. On sheets, the depth of metal above the line of contact of the exit rolls is an important factor.

The electrogalvanizing method of zinc coating is simply a zinc electroplating process. Modern practice makes possible the production of coatings of virtually any desired weight for outdoor or other severe service, and of bright thin coatings where appearance is the primary consideration.

In the deposition of both thick and thin coatings, as in other electroplating operations, cleaning of the surface is of major importance, and a considerable part of modern development in the art—particularly in the field of rapid deposition—relates to cleaning. Parts supplied for bright zinc plating normally carry only a film of grease and drawing lubricant, which is removed by cathodic treatment in an alkaline solution. Flat and round steel wire and continuous sheet, furnished for rapid plating at high current density, may carry a film of rust, which, when removed by suitable acid treatment, leaves a film of undissolved or redeposited material that must be removed before plating. An alternative method, involving electrolytic treatment in molten caustic soda, has been used commercially.

Rapid electrodeposition is obtained by the use of current densities as high as 1000 amp per sq ft in conjunction with very pure electrolytes.

The replenishment of the zinc in this process is accomplished by one of two means. In one process, zinc ore is leached with sulfuric acid to abstract the zinc. The resulting solution is too impure for electrolysis at high current density and requires removal of the impurities before use. Insoluble anodes (usually of a lead alloy) are employed in the electrolysis. In the less highly acid solutions zinc is supplied directly in the form of anodes of high-purity zinc, which are readily available. Each method has its own advantages but relatively few data are available concerning comparative costs.

Solutions for applying bright lustrous deposits are of the alkaline cyanide type, containing various organic and inorganic ingredients to promote brightness. In one process brightness and high luster are obtained solely by maintaining the electrolyte in a state of very high purity. In all processes the zinc content is supplied by means of zinc anodes. In the industry the consensus is that zinc of high purity is required for best results.

Electrogalvanized coatings consist of a single layer of zinc with no layer of alloy. As a result, these coatings are very adherent when bent, regardless of thickness, unless the preliminary cleaning was not thorough. Electrogalvanizing offers the advantage, important in many cases, of requiring no heating of the steel. Also it is claimed that greater uniformity of coating can be obtained. This is probably true of wire, but on sheet some edge effect may occur, and on irregularly shaped material the difficulties of securing uniformity increase as with any plating process. The appearance of electrogalvanized coatings is considered preferable in some applications. The practical range of coating thickness obtainable by electrogalvanizing is greater than by hot dipping, but little information is available concerning relative costs of comparable weights of coating applied by the two methods.

An important new field in the application of galvanized steel has been opened by the advent both of electrogalvanized steel wire, strip and sheet, and of the same products coated by improved hot dipping methods to yield heavy adherent coatings. Many articles that could be given adequate protective coatings of zinc only by relatively expensive methods of galvanizing after fabrication, can now be fabricated from heavily coated stock. Weaving of such wire and deep drawing of heavily coated sheet are now commercially practical.

Sherardizing, described on page 715, a third method of coating zinc, produces coatings consisting entirely of iron-zinc alloy, uniformly distributed.

Spray coating, described on page 720, should be mentioned here since it affords a means of zinc coating parts too large for treatment by any of the other methods. Like electrogalvanizing, spray coating involves no heating of the steel.

Zinc Impregnation

By F. C. Kelley*

THE PROCESS of zinc impregnation dates from an English patent obtained in 1901 by Sherard Cowper-Coles and is called "sherardizing" to honor the inventor.

Apparatus. In order to minimize oxidation of the zinc, this process should be carried out in tightly sealed drums, which are rotated in gas-heated or oil-heated furnaces to produce a uniform coating of high density. Electrically heated drums that have properly insulated double walls are also used. The electrical heating units are placed between the walls of the drum, which is supplied with several coarse wire-screen containers so that the work pieces in any container may be removed at any time. The drums are not completely filled with powder. This allows the parts under treatment to rub against one another and the powder to change its position, ensuring close contact with the charge.

The Zinc Powder. The zinc dust should be as free as possible from impurities, especially lead. However, small amounts of silica or iron oxide do not seem to be deleterious. Periodic chemical analyses are necessary, and on the basis of the results, the metallic zinc content is maintained between 80 and 92%; the remainder is zinc oxide and impurities. A common method used for determining the amount of metallic zinc in the powder, depends on displacing hydrogen from sulfuric acid.

Table I. Results of Typical Analyses of Dust Used in Zinc Impregnation

Metal or Compound	Percentage in New Dust	Percentage in Used Dust
SiO_2	Trace	0.43
Cu	0.01	Nil
Pb	0.99	0.81
Fe	0.39	1.16
Cd	Nil	Nil
Zn	97.98	84.50
ZnO	0.46	12.12
Total Zn	98.34	94.57

Results of typical analyses of new and used dust are listed in Table I.

Before the metal to be coated has been charged, new powder is heated alone in the drums for a sufficient time to oxidize somewhat, so that the zinc content comes within the specified range. Used powder is analyzed frequently and some new powder is added when necessary, to keep the zinc content above 80%. The iron and iron oxide must be removed from the mixture periodically by magnetic separation in order to maintain the uniform quality of the coating. The particle size varies in zinc powder of the composition given above; results of screen analysis are shown in Table II. Some of this zinc dust has a particle size as small as 1/40,000 to 1/50,000 in.

Table II. Particle Size of Zinc Powder

Screen	Percentage Zinc
On 100-mesh	3.65
On 150-mesh	1.05
On 200-mesh	3.55
On 350-mesh	6.25
Through 350-mesh	84.50

Powder that has a zinc content of 90% gives a coating of specific gravity 6.75 when a temperature of 660 to 700 F is used. The powdered alloy $FeZn_{10}$ has been used to a limited extent, but the temperature must be higher than that for powdered zinc.

In the early process, sand was added to the powder to prevent caking at the higher temperatures, and a small amount of carbon was added to limit the oxidation of the zinc.

Temperature. The wide range of temperatures originally used, caused widely varying results. Today the process is usually carried out within the temperature range from 660 to 700 F, which gives a satisfactory product. Lower temperatures result in a thinner coating, while higher temperatures produce a coating that has a greater iron content and somewhat lower resistance to atmospheric exposure. The duration of treatment varies from 3 to 12 hr, according to the desired thickness of coating.

If the operating temperature is much above 660 to 700 F, the coating will be coarsely crystalline; if the temperature is much below that range, the coating will be relatively soft and porous. For the best coating, the charge should be heated as rapidly as possible to between 660 and 700 F. When electrically heated drums are being used, rapid heating can be obtained by the use of parallel series connections to the heater units.

The Coating. The coating is ordinarily gray, but when cleaned by brushing or rubbing, the color is nearly that of pure zinc.

Usually only one structural layer is observed on the surface of the iron, but after the zinc-impregnated iron has been heated to higher temperatures, a second layer is sometimes found. Opinions differ concerning the composition of the single-phase layer; some assert that it is $FeZn_7$, and others, $FeZn_{10}$. McCulloch found that after iron foil had been heated in zinc dust for 45 days at 779 F, the alloy formed contained about 6% Fe. He obtained about the same result on a similar piece of iron foil heated for two days at 689 F. Accordingly, he concluded that the limit of the iron-zinc solid solution is 6% Fe, instead of the higher percentage usually shown in the phase diagram. McCulloch gave 8 to 10% as the average iron content of good sherardized coatings.

When the second layer appears it is much richer in iron, and Rawdon has suggested that it might be $FeZn_3$.

All sherardized coatings are fissured with minute cracks, which probably result from the large differences in expansion between the coating and the iron base.

The thickness of the coating produced in 3 hr at 660 to 700 F is about 0.0025 in.

The Cementation Process. Some have stated that in the cementation process, the coating is deposited directly from the vapor phase; others believe that the coating is formed on contact between the metal and the zinc powder.

Several years ago Kelley investigated the possibility of improving the process by carrying out the operation in a vacuum of 1-mm pressure. It was found that there was little if any difference in the thickness or character of the coating if the charge was revolved, as compared with samples produced in the usual way. This would seem to indicate that the coating is formed largely through contact of the powder with the iron. The vapor pressure of zinc is probably high enough to give a slight coating, but not high enough to produce the thickness obtained in the usual process. The results of Trood, who obtained a much heavier coating in vacuum in a shorter length of time, have not been confirmed. The fact that particles of iron oxide and silica are sometimes found embedded in the coating supports the theory that the coating is formed by contact.

The Weathering of Sherardized Coatings. All sherardized coatings are anodic toward the iron with which they are in contact; however, they are less anodic than pure zinc. Burgess found that the potential of the alloyed coating with respect to iron was 0.20 to 0.25 v as compared with 0.50 v for zinc. This accounts for the protective value of the zinc coatings.

Coatings with low iron content gradually darken during weathering and finally become almost black, but those with higher iron content become reddish because of the oxidation of the iron. The red color is deceptive and does not necessarily mean that the iron underneath has been attacked. In general, however, coatings high in iron do

* Research Laboratory, General Electric Company, Schenectady

not resist the action of the atmosphere so well as those with lower iron content. The coatings high in iron will rust almost immediately in salt spray, while those low in iron will stand up well. Coatings that contain 15 to 20% Fe, break down rapidly when exposed to the action of the atmosphere, while those with 8 to 10% Fe or less stand up well. The life of a good sherardized coating depends also on the thickness. According to the 1936 report of ASTM Committee A 5, sherardized, hot dipped, and plated zinc coatings of the same thickness have about the same service life in similar environments.

Uses. A sherardized coating is very nearly uniform in thickness and so can be used on threaded parts like bolts and nuts. The threads are not filled up as they are by hot dip galvanizing. Allowance can be made for the coating when the threads are cut and, after sherardizing, rethreading or tapping is not necessary.

The principal application of sherardizing is for small steel parts, such as bolts, nuts and washers, or for castings that must resist the action of the atmosphere. Iron wire has also been coated, but the heavy coatings are brittle and may flake when the wire is bent sharply. However, processes have been perfected for producing on steel sheet and wire, a coating similar to a sherardized coating, in that it consists substantially of iron-zinc alloy. The process, known under various trade names, consists in heat treating a zinc coating produced by conventional hot dip galvanizing and thus converting it into iron-zinc alloy. Superior merit is claimed for this material, especially for ovens and other articles to be used at elevated temperature; wire so treated is used under atmospheric conditions.

Electroplated Metal Coatings

By William Blum*

IN THIS SECTION concerning the selection, application and testing of plated coatings, factors are summarized that are likely to be of interest to metallurgists and engineers who are not engaged directly in plating operations. Persons actually engaged in plating will require much more detailed information, which can be found in the textbooks and journal articles referred to.

Since almost all the metals applied by electroplating are nonferrous, these plating processes might be classified under nonferrous metallurgy. Although plating is applied extensively to copper, brass, nickel brass, zinc, zinc-base die castings, and aluminum, actually the largest part of commercial plating is applied to iron and steel; consequently the important commercial plating processes will be summarized in this section, with appropriate references to their applications to either ferrous or nonferrous metals.

The Selection of Electroplated Coatings. The choice of a coating—plated or not—for a specific purpose, depends on the advantages and limitations of that coating. "Electroplating" has been defined as the electrodeposition of an adherent coating upon an electrode for the purpose of securing a surface with properties or dimensions different from those of the base metal. Among the specific reasons for applying plated coatings are the following:

1 To produce and retain ■ desired appearance, for example, color and luster. This requirement usually also involves resistance to tarnish. In general (unless lacquer is applied subsequently) this aim can be accomplished by plating with the noble metals, such as platinum and gold; or with less noble but passive metals, such as nickel and chromium. Silver resists oxidation but is readily tarnished by sulfur compounds; copper is tarnished both by oxygen and sulfur.

2 To protect the base metal against corrosion. Because uncoated iron usually rusts during exposure to the atmosphere, it is customary to apply some protective coating. Plated coatings may protect iron in either of two ways.

(a) The coating may be less resistant to initial corrosion than iron. Therefore it may protect small exposed areas of iron by electrolytic action, in which process the coating is anodic (that is, it dissolves) and the base metal is cathodic (that is, it is protected against corrosion). The two anodic metals that are applied commercially are zinc and cadmium. Coatings of both these metals furnish prolonged protection to steel in mild or marine atmospheres, but are attacked rather rapidly in industrial locations where sulfur compounds are present. When exposed to industrial atmospheres, zinc coatings last longer than cadmium coatings of the same thickness.[1] Both zinc and cadmium coatings afford protection approximately proportional to the thickness. Electroplated zinc furnishes about the same protection as zinc coatings of the same thickness that are produced by hot dipping or sherardizing.[2] One objection to zinc coatings is that under marine or tropical conditions, bulky white corrosion products are formed. Various chromate treatments are used to retard this corrosion of the zinc.

(b) The coating may be more resistant to initial attack than the steel. This is true of copper, nickel, tin, lead, chromium, silver, gold and nearly all electrodeposited metals except zinc and cadmium. Such coatings furnish complete protection to the base metal only if they are impervious. If any pores exist, corrosion of the steel beneath them is usually accelerated. The most practicable method of decreasing the porosity and increasing the protective value, is to increase the thickness of the coating.[3]

Of these more resistant metals, nickel is most commonly used to protect steel against corrosion. A preliminary coating of copper is frequently applied, partly because the copper may be more cheaply polished than the underlying steel or the superposed nickel. The customary thin, ornamental layer of chromium increases the resistance to tarnish, but adds little to the protection against corrosion. Tin and silver coatings are used largely because of their resistance to foods and beverages. Lead is generally applied for resistance to sulfuric acid, but under many conditions furnishes good protection against corrosion of steel.

All plated metals applied commercially to zinc or aluminum are more noble than these base metals, and must therefore be thick enough to be nearly impervious in order to furnish good protection against corrosion. As a first approximation, about the same thickness of nickel or of copper plus nickel is required on zinc as on steel. On less corrosive base metals, such as copper and brass, thinner coatings of nickel are usually adequate.

The electrochemical series of equilibrium potentials is an approximate guide to the ability of a metal coating to protect other metals against corrosion, but in practice there are many exceptions. Although the accepted standard potential of cadmium is less negative (more noble) than that of iron, a cadmium coating protects iron that is exposed through small pores. On the other hand, under equilibrium conditions, chromium is more negative (less noble) than iron, but because chromium becomes passive in the air, it accelerates the corrosion of exposed iron.

3 To protect a base metal against some specified chemical reaction. The most extensive use of this type of coating is in copper plating to prevent certain parts of steel articles from absorbing carbon during case hardening. Experience indicates that the thickness of copper coating determines the protection afforded for any given period and temperature of carburizing.[4] It is probable that the increased thickness is more effective as a result of reducing the porosity.

A similar application, usually confined to laboratory

* Chemist, National Bureau of Standards, Washington, D. C.

practice, is the use of silver coatings to protect steel against oxidation during heat treatment. Chromium is helpful but apparently not equal to silver for this purpose.

Nickel-plated steel is used in alkaline storage batteries and oxygen-hydrogen cells because nickel resists alkaline solutions. Nickel and chromium coatings are used in the manufacture of films and plastics because these metals resist most organic compounds. Heavy silver coatings are used under thin layers of lead and indium on airplane bearings. Such coatings are very resistant to corrosion by the lubricants.

4 To protect the base metal against wear caused by either abrasion or erosion. ("Erosion" is used here in the same sense as "surrosion", that is, the combined result of corrosion and abrasion.) Resistance to abrasion requires that the coating shall be harder and tougher than the base metal. Protection against erosion involves also ability to resist chemical attack by the surrounding medium. Chromium more nearly meets these requirements than any other single plated metal and is used extensively for resistance to wear on gages, dies, molds, printing plates, and certain cutting tools.

5 To increase the dimensions. This process, known as "building up", may be applied to parts accidentally made undersize, or to worn parts. To serve this purpose, coatings must be at least as hard as the metal to which they are applied. The three metals commonly used are iron, nickel and chromium. Iron has the advantage of cheapness (significant in large-scale operations) and ability to be case hardened subsequently. Nickel is the most easily applied, and the hardness can be controlled over fairly wide limits. Chromium is most commonly used when greater resistance to wear is desired than can be secured with the base metal alone. In practice, the two difficulties that have limited the use of the building-up process (especially in the United States, with high-priced labor) are the selection and application of suitable "stop-offs" to prevent deposition on areas not to be built up, and the care needed to secure consistently the high degree of adhesion usually required.

The Specification and Testing of Plated Coatings. The principal properties of coatings that determine their value and may therefore serve as a basis for specifications are (1) thickness, either average or minimum, (2) porosity, (3) adherence, (4) hardness, (5) luster and reflecting power, (6) protection against corrosion.

1 Thickness. The *average thickness* is estimated by stripping (dissolving) the coating from a known or measured area, and determining the amount of removed metal by loss in weight or by chemical analysis of the resultant solution. The average thickness was formerly the basis of most plating specifications, but now it is being replaced by requirements for a certain minimum thickness on significant surfaces.

The *minimum thickness* or the thickness of coating at any point, may be measured by the following methods: (*a*) microscopic examination of a suitable cross section;[5] (*b*) the "chord" method,[6] in which the coating is cut through with a grinding wheel of known radius; (*c*) methods depending on rate of chemical reaction, such as the Preece test for zinc coatings,[7] the "spot" test with concentrated HCl for chromium coatings,[8] the "dropping test" for zinc and cadmium deposits,[1] and the "jet" test for nickel coatings;[9] (*d*) nondestructive magnetic methods that depend either on the attraction of a magnet to the coating[10] (for example, to nickel on a nonmagnetic base metal) or on the reduction in attraction of the magnet by the presence of a nonmagnetic coating[11] such as copper, zinc or chromium on a magnetic base metal such as iron or steel. Of these methods the microscopic is the most reliable (except for very thin coatings) and is usually the basis of umpire tests.

The minimum thickness obtained on a given article depends on the average thickness and can be controlled by the time and current density used. The minimum thickness depends also on the distribution of coating, which varies according to the throwing power of the solution, as well as the shape of the article and the position of it with respect to anodes and racks.

2 Porosity. Small pores have little significance in zinc and cadmium coatings that are more than 0.0002 in. thick. Porosity in coatings of more noble metal on steel may be detected and estimated approximately, by some form of ferroxyl test such as the ferroxyl paper,[12] and by the boiling water test,[13] but the results are not sufficiently accurate to be used in specifications. With the noble coatings, the salt spray test is principally a measure of porosity.

3 Adherence. Poor adherence can be detected by deforming the specimen—for example, by bending, twisting, hammering, extruding, or stretching. These methods do not yield quantitative results. The methods of Ollard[14] and Jacquet[15] for measuring adhesion require special specimens and are not applicable to finished products. An excellent review of methods for measuring adherence was published recently by A. L. Ferguson and L. F. Stephan.[19]

4 Hardness. Most of the customary methods of measuring hardness (*see* page 93) are directly applicable to plated coatings only when the coatings are much thicker than those used commercially, because with thin coatings the results are influenced by the base metal. The results from thick coatings do not necessarily represent the properties of the thinner coatings usually applied in commercial plating. Measurements show that for each plated metal it is possible to vary and control the hardness over a fairly wide range by altering the conditions of deposition. For example, electrodeposited nickel and iron vary from about 150 to 400 Bhn, and chromium varies from about 500 to 900 Bhn. No simple correlation has been found between the results of each hardness test and the behavior in service.[16] Where wear is caused principally by abrasion —for instance, on intaglio printing plates—the scratch hardness is at least approximately proportional to the wear resistance.

5 Luster and Reflecting Power. Egeberg and Promisel[17] express the brightness of a plane surface as the ratio of the specular reflection (in which the angle of reflection is equal to the angle of incidence, 45 deg in their tests) to the diffuse reflection (that is, the reflection at all other angles). This method is applicable only to plane specimens but may be useful in research, especially on deposits from "bright plating" solutions.

6 Protection Furnished Against Corrosion. Continuous exposure in typical atmospheres[1, 3] yields results that are closely related to the life in similar service, but such tests require months or years. Accelerated corrosion tests are useful for comparing the behavior of similar coatings under conditions corresponding to those in the test.[1, 12] For example, the salt spray test yields results that may be similar to those in marine but not in industrial locations.

Typical Specifications. Tentative specifications adopted by the American Electroplaters' Society and the American Society for Testing Materials[18] are summarized in Table I.

Important Factors in Electroplating. The quality, including appearance, adhesion, porosity and protective value of electroplated coatings, depends on numerous factors, such as:

Base Metal. It is not possible to apply high-quality coatings to poor-quality metals. The composition of the base metal should be known and controlled. The structure of the base metal may affect the reactions in cleaning and pickling processes and the structure of the coating. The *condition of the surface,* including the degree and nature of the polishing processes, and the presence of pores, cracks, or inclusions, may have a direct bearing on the character and porosity of the coatings. However, with "clean" cold rolled steel, marked differences in the method or the extent of polishing have little effect on the protective value of subsequently plated coatings.[20]

Preparation for Plating. It is necessary to have the base metal surface chemically clean in order to secure good adhesion of deposits. The preparation usually involves "cleaning", that is, removal of grease and foreign particles; and "pickling" (for steel) or "dipping" (for nonferrous metals) to remove oxides or other compounds, including adsorbed alkali, and in some instances to etch the surface.

Electrodeposition. The principal variables that are subject to control in the plating process are listed on the next page.

1 *The composition of the bath,* including the concentrations of major constituents and of objectionable impurities, is of primary importance. In general, it is necessary to keep the major constituents constant only within plus or minus 5% of the amounts present; analytical methods that are accurate to plus or minus 2% are usually adequate. The permissible content of each impurity must be determined by experience under the conditions employed. The acidity or pH should be controlled in all except very strongly acid or alkaline solutions.

2 *The temperature of the bath* should be kept within specified limits, which are narrower for chromium than for other plating baths.

3 *The average current density* must be kept within desired limits for the sake of uniformity in thickness and quality of coatings.

4 *Agitation* permits an increase in the current density in many baths. Some agitation is secured by the movement of oscillating rods or continuous conveyers, but stronger agitation is sometimes obtained by using air, or rotating the electrodes.

5 *Filtration,* either continuous or intermittent, is often used to keep the solution free from suspended matter. Filtration is especially desirable if agitation is used or if very thick deposits are applied.

6 *The anodes* should ordinarily be of such composition and structure as to maintain the metal concentration and the pH; that is, the anode efficiency should be nearly the same as the cathode efficiency. In chromium plating and a few other operations where insoluble anodes are used, the metal content is maintained by replenishment.

Table I. Summary of ASTM Tentative Specifications for Electroplated Metal Coatings

	DS	FS	KS	QS
Nickel and Chromium Coatings on Steel				
Type				
Minimum thickness on significant surfaces, in.				
Copper plus nickel	0.0020	0.00125	0.00075	0.0004
Final nickel	0.0010	0.0006	0.0004	0.0002
Chromium (if required), in.	0.00001	0.00001	0.00001	0.00001
Salt spray, continuous exposure, hr.	96	72	48	16
Zinc Coatings on Steel				
Type		GS	LS	RS
Minimum thickness on significant surfaces, in.		0.001	0.0005	0.00015
Cadmium Coatings on Steel				
Type		NS	OS	TS
Minimum thickness on significant surfaces, in.		0.0005	0.0003	0.00015
Nickel and Chromium Coatings on Copper and Copper Alloys				
Type		FC	KC	QC
Minimum thickness on significant surfaces, in.				
Nickel		0.0005	0.0003	0.0001
Chromium (if required)		0.00001	0.00001	0.00001
Nickel and Chromium Coatings on Zinc and Zinc Alloys				
Type		FZ	KZ	QZ
Minimum thickness on significant surfaces, in.				
Copper plus nickel		0.00125	0.00075	0.0005
Copper (if present)		0.0004	0.0003	0.0002
Final nickel		0.0005	0.0003	0.0003
Chromium (if required)		0.00001	0.00001	0.00001
Salt spray, continuous exposure, hr		48	32	16

Equipment. *Electrical.* Most commercial plating is conducted with motor-generator sets, usually with potentials from 6 to 12 volts, and with current outputs depending on the area of work to be plated and the current density. In recent years many large rectifiers have been used for plating, principally of three types—copper oxide, copper sulfide and selenium.

Tanks. Wooden tanks are used principally for rinse tanks. Steel tanks are used for alkaline cleaning baths and for cyanide plating baths. Steel tanks lined with rubber or plastics, are used for acid pickles, acid copper baths, and nickel baths. Lead-lined steel or wood tanks are satisfactory for sulfuric acid solutions, acid copper, and chromium baths. Tanks lined with acidproof brick are used for pickling and chromium plating. Acidproof stoneware is used for dips containing nitric acid and for small plating baths. Enamel-lined tanks are suitable for small baths.

Typical Plating Baths and Conditions. The following concentrations and conditions are typical, but changes may be required in order to meet specific needs.

1 Copper Plating

Acid bath, used in electrotyping, and for intermediate layers of copper, or for copper on brass.

	oz per gal
Copper sulfate, $CuSO_4.5H_2O$	33
Sulfuric acid, H_2SO_4	8

Temperature, 75 to 120 F
Current density, 20 to 40 amp per sq ft

Additions of organic matter are made to produce smoother or harder deposits.

Cyanide bath, used for plating copper directly on steel, as well as on brass or zinc.

	oz per gal
Copper (cuprous) cyanide, CuCN	3
Sodium cyanide, NaCN	4.5
Sodium carbonate, Na_2CO_3	2
(Free sodium cyanide), NaCN	1

Temperature, 95 to 120 F
Current density, 3 to 15 amp per sq ft

Rochelle salt – cyanide bath, used especially for plating copper on zinc die castings.

	oz per gal
Copper cyanide, CuCN	6
Total sodium cyanide, NaCN	7.5
Free cyanide, NaCN	0.75
Rochelle salt, $NaKC_4H_4O_6.5H_2O$	6
Sodium carbonate, Na_2CO_3	4

Temperature, 130 F
Current density, 20 to 30 amp per sq ft

2 Nickel Plating

Plating on steel or brass at low current density.

	oz per gal
Nickel sulfate, $NiSO_4.7H_2O$	16
Ammonium chloride, NH_4Cl	2
Boric acid, H_3BO_3	2

pH, 5.3
Temperature, 70 to 90 F
Current density, 10 to 20 amp per sq ft

Plating on steel or brass and over copper on zinc, at high current densities.

	oz per gal
Nickel sulfate, $NiSO_4.7H_2O$	30 to 40
Nickel chloride, $NiCl_2.6H_2O$	6
Boric acid, H_3BO_3	4

pH – high pH, 5.0 to 5.2
– low pH, 2.0 to 2.5
Temperature, 100 to 150 F
Current density, 25 to 50 amp per sq ft

Many organic materials are added to produce "bright nickel" deposits now used extensively.

Plating directly on zinc die-castings.

"High-Sulfate Bath"

	oz per gal
Nickel sulfate, $NiSO_4.7H_2O$	10
Sodium sulfate, Na_2SO_4	15
Ammonium chloride, NH_4Cl	2
Boric acid, H_3BO_3	2

pH, 5.5
Temperature, 70 to 80 F
Current density, 20 to 30 amp per sq ft

3 Chromium Plating

	oz per gal
Chromic acid, CrO_3	30 to 50
Sulfuric acid, H_2SO_4	0.3 to 0.5

(The sulfuric acid, or an equivalent amount of any soluble sulfate, should be in such concentration that the ratio CrO_3/SO_4 is about 100
Temperature, 100 to 160 F
Current density, 60 to 500 amp per sq ft

The temperature and current density should be related so as to give a cathode efficiency of about 12% for bright deposits and 16% for hard deposits. In general, the current density must be increased as the temperature is raised and must be slightly higher for hard deposits than for ornamental coatings. For example, at 113 F, current densities from 100 to 150 amp per sq ft yield bright deposits, while current densities from 150 to 200 amp per sq ft yield slightly dull but harder coatings.

4 Zinc Plating

Acid Bath

	oz per gal
Zinc sulfate, $ZnSO_4.7H_2O$	50
Aluminum chloride, $AlCl_3.6H_2O$	3
Sodium sulfate, Na_2SO_4	10

pH, 3 to 4
(Organic agents are frequently added to produce brighter deposits.)
Temperature, 70 to 95 F
Current density, 20 to 50 amp per sq ft

Cyanide Bath

	oz per gal
Zinc cyanide, $Zn(CN)_2$	8
Sodium cyanide, NaCN	3
Sodium hydroxide, NaOH	7

(Various agents, both organic and inorganic, are often added to produce brighter deposits.)
Temperature, 70 to 95 F
Current density, 10 to 30 amp per sq ft

5 Cadmium Plating

	oz per gal
Cadmium oxide, CdO	6
Sodium cyanide, NaCN	16

(With organic and inorganic addition agents as brighteners.)
Temperature, 70 to 95 F
Current density, 10 to 30 amp per sq ft

6 Tin Plating

	oz per gal
Sodium stannate, Na_2SnO_3	12
Sodium hydroxide, NaOH	1
Sodium acetate, $NaC_2H_3O_2$	2
Hydrogen peroxide, H_2O_2 (25 vol)	0.3

Temperature, 130 to 160 F
Current density, 20 to 60 amp per sq ft

7 Lead Plating

	oz per gal
Basic lead carbonate, $Pb(OH)_2.2PbCO_3$	20
Hydrofluoric acid, HF (50%)	32
Boric acid, H_3BO_3	14
Glue	0.03

Temperature, 70 to 95 F
Current density, 10 to 20 amp per sq ft

8 Iron Plating

	oz per gal
Ferrous chloride, $FeCl_2.4H_2O$	40
Calcium chloride, $CaCl_2$	45

Temperature, 190 F
Current density, 50 amp per sq ft

9 Brass Plating

	oz per gal
Copper cyanide, CuCN	3.6
Zinc cyanide, $Zn(CN)_2$	1.2
Sodium cyanide, NaCN	7.4
Sodium carbonate, Na_2CO_3	4.0

Temperature, 90 to 120 F
Current density, 2 to 5 amp per sq ft

Specialized Applications of Electroplating. The applications of electroplated coatings are too numerous and varied to itemize. Nevertheless certain special applications warrant discussion because they involve unusual types of coatings or equipment.

Plating of Strip Metal or Wire. These processes differ from conventional plating methods by being continuous rather than intermittent. One of the largest developments of wire plating is the bethanizing process, in which steel wire is plated with zinc.[21] The procedure differs from other zinc plating in that insoluble anodes are used and the electrolyte is prepared by dissolving zinc ore or dross in sulfuric acid and purifying the resultant solution very carefully. Special methods are employed for cleaning the wire, including cathodic treatment in a bath of molten caustic soda. The wire passes successively and continuously through the cleaning, pickling and plating baths. Because of the rapid movement of the wire, and the high acidity of the bath, it is possible to use very high current densities; for example, more than 1000 amp per sq ft. Largely because of their high purity, these zinc coatings are very ductile.

Similar equipment is used for continuous plating of wire with tin, copper or other metals. However, soluble anodes are generally used with these metals.

During World War II, scarcity of tin led to the extensive production of "electrolytic tin plate",[22,23] because thinner coatings can be applied by plating than by the hot dipping method commonly used. The latter method usually produces coatings with from 1.5 to 2 lb Sn per base box, corresponding to a thickness of 0.00009 to 0.00012 in. Sn. Much of the electrolytic tin plate carries a coating of only 0.5 lb Sn per base box, or 0.00003 in., although thicker coatings also can be applied by plating. Electrotinning is discussed in the article on page 709.

Hard Chromium Plating. The extreme hardness, low coefficient of friction, and resistance to wear and chemical attack of electrodeposited chromium have led to its extensive application to dies, gages and tools. This process is commonly referred to as "hard chromium plating" or "industrial chromium plating" to distinguish it from ornamental plating. The hard chromium coatings are relatively thick, usually from 0.0003 to 0.010 in., and are applied directly to the base metal, generally steel, in contrast with the decorative coatings, which are from 0.00001 to 0.00005 in. thick, and are almost always applied over a coating of nickel. The baths and conditions of deposition are not essentially different, though slightly higher current densities are generally used for the industrial coatings. In both applications the chromium usually has a hardness of 850 to 950 Bhn.

Because of the more severe mechanical conditions of service, it is important to achieve the best possible adherence of the chromium. A typical cycle involves the following steps in plating steel with hard chromium:

1 Removal of grease by an organic solvent
2 Electrolytic cleaning in an alkaline solution, first as cathode, then as anode
3 Anodic etching in chromic acid or sulfuric acid
4 Stopping-off areas not to be plated
5 Racking, if necessary, with auxiliary anodes so as to produce a nearly uniform current density on the parts to be plated
6 Plating for the required period
7 (Especially on high carbon steels) heating at about 200 C (392 F) to expel hydrogen
8 Grinding or lapping, if necessary, to produce the desired dimensions.

More details of these operations are described in a Recommended Practice of the ASTM.[25]

Porous Chromium.[26,27] A special process of hard chromium plating (the Van der Horst process) has been developed in recent years for use on cylinders and piston rings of aircraft and Diesel engines. The chromium deposit is made porous in order to retain oil and thereby aid lubrication and resist wear. In general, chromium is applied to the surface of the cylinder under conditions that yield hard deposits. The exact conditions are chosen that will lead to the desired type of porosity. The porosity is usually produced in a supplemental process by etching the chromium surface anodically in a chromic acid solution. In this process the chromium is not dissolved off uniformly, but in such a way as to reveal and enlarge the fine cracks that are present in the chromium as deposited. The result is the formation of a network of fine channels in the chromium surface, in which oil is subsequently held. The distribution of these channels, and the size of the "plateaus" between them, are used to define and specify this channel type of porosity. When the plateaus are very small, the etched surface has the "pin-point" type of porosity.

After the surface has been etched, it is usually honed down to the desired dimensions.

Sprayed Metal Coatings

By R. A. Ehrhardt* and A. Mendizza*

SPRAYED metal coatings are produced by use of an air blast to spray heated metal particles against the object to be coated. The impingement of the metal particles on a surface causes them to flatten and interlock, forming a continuous though somewhat porous coating. The chief advantages of metal spraying are the much greater rate at which the coatings are formed, in comparison with other methods of metal coating, and the portability of the equipment, which permits the coating of objects too large to be treated by other methods.

The process is particularly suitable for coating large structures, such as storage tanks, towers, dock gates, tank cars, turbines and bridges. It is also especially useful for applying thick coatings to limited areas, as in the rebuilding of worn parts such as bearings, shafts, pistons and cylinders, and in the reclamation of undersize parts in general. This process has also been applied, to a limited extent, in coating nonmetallic materials—wood, plastics and the like—for a variety of uses, frequently ornamental.

Sprayed metallic coatings are porous because of the method by which they are formed. For some purposes the pores must be filled, but for most purposes the greater thickness of the coatings makes this unnecessary. In some uses, particularly for bearings, porosity is advantageous, since it permits retention of a lubricant.

The density of the sprayed metal is less than that of the cast metal, as indicated in Table I.

Table I. Density of Cast and Sprayed Metal

	Density in Cast Form	Density of Sprayed Metal
Aluminum	2.70	2.31
Zinc	7.14	6.32
Tin	7.31	6.82
Copper	8.92	7.51
Lead	11.34	9.77
Brass	8.30	7.32
Bronze	8.76	7.77

The density of the coatings may be increased by working or by heat treatment.

The particles that form the sprayed coatings contain oxide and are slightly work hardened, a circumstance resulting in higher hardness than in cast metal. The scratch hardness of sprayed metal compares with that of cast metal as shown in Table II.

The adhesion of sprayed metal coatings to the base metal is generally much less than that obtained by other methods of application. In the absence of alloying or chemical action between the coating and the base material, it is essential that the surface of the base material be clean and roughened. The best results are obtained on freshly sandblasted surfaces that have sufficient roughness to anchor the deposit. For this purpose, hard sharp sand is essential. Preheating the surface sometimes improves the adherence. Babbitt gives excellent bonds when sprayed on tin-plated surfaces that have been heated to just below the melting point of tin. Etching the surface usually results in a less satisfactory bond than sandblasting, but etching after sandblasting improves the bond.

Table II. Scratch Hardness of Cast and Sprayed Metal

	Width of Scratch in Millimeters	
	Cast	Sprayed
Tin	0.08	0.056
Aluminum	0.06	0.044
Zinc	0.05	0.032
Copper	0.05	0.029
Brass	0.05	0.032
Bronze	0.023	0.025

Resistance to Corrosion. Sprayed metallic coatings are often used where protection against corrosion is an important factor. Although sprayed coatings are generally considerably thicker than coatings produced in other ways, inherent porosity limits the application of sprayed coatings to specific uses.[16]

In general, metallic coatings may be either electronegative or electropositive toward the base metal. Zinc, aluminum and cadmium are of the electronegative type and protect more noble metals by sacrificing themselves. For this reason, it is not necessary that such coatings be completely free from pores. On the other hand, electropositive metals, such as nickel, stainless steel, copper, tin or lead, must be relatively free from pores when used over metals such as iron or steel, since otherwise the underlying metal would dissolve anodically through the imperfections and pores in the coating.

When zinc, cadmium and aluminum are sprayed on ferrous metals, the thickness of the coating ordinarily ranges from 0.004 to 0.012 in., depending on the severity of exposure. Sprayed zinc and cadmium coatings, as thin as 0.0012 in., afford considerable protection to steel or iron in sea water. In order to enhance the protective value of porous coatings, it is sometimes advantageous to impregnate the pores with a good phenolic resin varnish. Silicates have also been used as impregnants for certain specific applications.

Metals sprayed in neutral atmospheres, such as nitrogen, are generally denser, more adherent and ordinarily more resistant to corrosion than those produced by the use of compressed air. Because of the absence of oxygen, coatings produced in inert atmospheres are free from oxide and are therefore more uniform electrochemically; whereas coatings produced by the compressed-air method are composed of myriads of oxide-coated metal particles, which, under proper conditions, constitute as many galvanic cells. Under such conditions, the metal will tend to corrode anodically, because it is more electronegative than the oxide. Coatings of aluminum, chromium steels and stainless steels, when sprayed in neutral atmospheres, have been successful in preventing corrosion by hydrogen sulfide gas.[12]

Soft coatings, such as lead, may be strengthened mechanically by rolling. This method has proved advantageous in preventing corrosion by sulfuric acid. Rolled lead coatings 0.002 in. thick will protect baser metals against 70% H_2SO_4 at temperatures as high as 80 C. Slightly thicker coatings are used for more dilute acid.[16] Slip areas of riveted joints have been sprayed with light metals to replace linseed oil and red lead.[24] This process, although more effective, has the disadvantage of being considerably more expensive. Metal spraying has been

used to some extent on spring steel parts in order to avoid hydrogen embrittlement, generally associated with processes for depositing metal electrolytically.[18] Aluminum, high-carbon and low-carbon steels, lead, monel, red brass and stainless steels have been employed successfully for the prevention of corrosion in the oil industry. Aluminum coatings on steel have remained unimpaired in cracking units after 4½ years, as compared with previous losses of 0.036 in. of metal per year.[22] Aluminum is also used for protecting iron and steel parts that are to be exposed to high temperatures—grate fingers, stacks and certain superstructures of boats. Coatings from 0.006 to 0.010 in. thick are used on these parts.

Reclamation of Undersized and Worn Parts. Metal spraying is frequently used for reclaiming worn or undersized parts. Since the sprayed metal is harder than the original metal and retains oil better, the reclaimed parts are usually superior to the original surfaces in performance. In this application, adhesion is extremely important and the surfaces to be coated are usually rough turned on a lathe or are rough threaded to improve the bond. The parts are then sprayed oversize, turned and ground to size. For special purposes the new coating can be selected to provide greater resistance to wear and to corrosion than is afforded by the base material. Metal spraying is also used for hard surfacing light metal members where a combination of light weight and resistance to wear is desired.

Sprayed metal coatings have been used for providing shields and the grounding of electrical equipment such as vacuum tubes, and for producing metal-to-glass seals in hermetically sealed meters and the like. To facilitate bonding, the glass is preheated before the metal is sprayed.

Hard Surfacing. Certain alloys, for example nickel-base alloys that contain chromium and boron, may be sprayed onto a surface desired to be hard, and the coating may subsequently be melted and alloyed with the base metal by torch, furnace or induction heating, in order to provide a hard, wear-resisting surface. Coatings as thick as 0.060 to 0.075 in. have been sprayed economically. When a greater thickness is needed, welding is usually preferable as a method of hard facing.

Methods of Application. Two methods of producing sprayed metal coatings are in general use—the wire gun method sometimes referred to as "Schoop Spraying", and the powder method. Because of the availability of metals in wire form, the wire gun method is the more commonly used. The metal, in the form of wire, is fed into an oxyhydrogen or oxyacetylene flame by means of an air-driven turbine of variable speed. The wire is fed into the flame at a speed just sufficient to permit melting, and the molten metal is then atomized and projected by an air blast surrounding the flame. If the metal melts too soon, it is oxidized excessively; if it does not melt soon enough, it is projected in lumps of various sizes. Formerly, most of this spraying was done with a hand gun weighing a few pounds, but recently a larger gun, designed for mounting on the tool post of a machine, has come into more general use. The machine-mounted guns are capable of handling wires as large as $\frac{3}{16}$ in. in diam and can be controlled more accurately than the hand guns, which are limited in design by the weight factor. Any metal that can be made in wire form and melted in the flame, can be sprayed.

In the powder method, the metal is supplied in the form of a fine powder that is carried into the flame by suction produced in the nozzle of the gun. This method, particularly suitable for metals that cannot be produced readily in wire form, can also be used for spraying nonmetallic materials, such as plastics and rubberlike substances, as well as mixtures of metal powders and mixtures of metal and nonmetal powders. Because of the added cost of producing metals in powdered form, powder is not ordinarily used where the wire gun is satisfactory. However, the application of powder is very economical of material, because the flow of metal can be stopped promptly by breaking the suction between the pistol and the container—an action that requires merely removing the thumb from an orifice on the head of the pistol.

Health Hazards.[25] In the spraying of metal coatings, some material misses the mark or bounces off and is entrained in the air as fine metal particles, usually with a superficial coating of oxide. Obviously this is one of the easiest ways to suspend finely divided metals in air, where they may be inhaled easily by anyone present. Therefore, if the metals used for coating are toxic, the operator of the spray gun and his helper should be protected by respirators that have been approved by the Bureau of Mines for this special work. If there is any question concerning the efficiency of the respirator for this particular job, it would be better to rely on air-supplied masks.

For information on health risks involved in spraying any particular metal, the reader may refer to the article on page 755 in this Handbook.

Facing or Surfacing by Welding

By C. W. Obert*

FACING or hard surfacing is a process of welding onto a wearing part, a layer, edge, or point of a metal that is resistant to abrasion or corrosion. Hard facing has proved to be an easy and economical means of keeping equipment in good operating condition. There are also soft surfacing operations—for example, the application of a bronze bearing metal.

Hard Facing. Hard facing was applied originally to metal-working dies, oil-well drilling tools, and certain types of excavating equipment. Numerous other applications have been found and hard facing is now an important factor in the welding industry.

The principal cost-reducing features of hard facing are (1) longer life of equipment, (2) fewer replacements with resultant saving in labor charges and lost production time, (3) utilization of low-price base metal for wearing or corroding parts, (4) salvaging of worn parts, (5) savings in power consumption and (6) general increase in operating efficiency.

No single grade of hard facing material is suitable for all applications. To secure hardness, toughness, resistance to shock, resistance to corrosion, and other desired qualities, alloys of widely different compositions have been developed. These may be classified in groups, as follows. Although the resistance to wear of the materials in the various groups increases, in general, from one group to the next (those of Group 1 being lowest in wear resistance) this is not invariably true. The conditions of wear may reverse the order.

Group 1. Alloy Steels That Contain Less Than 20% of Alloying Elements. Alloying elements used are mainly chromium, tungsten, manganese, silicon and carbon. Although not so hard as higher-priced hard facing metals, alloy steels of this group possess greater toughness and resistance to shock. They have much greater resistance to wear than low-carbon steels and some compare favorably with Hadfield's high-manganese steel in this respect. Certain low-priced alloys, such as low-alloy cast iron, might be listed, but they are not used widely.

Group 2. Ferrous Alloys That Contain More Than 20% of Alloying Elements. Chromium, tungsten, manganese, silicon, carbon, and sometimes cobalt, nickel and other elements are used in these alloys, which are higher in price than those of Group 1. However, high hardness and greater resistance to abrasion ensure longer service for alloys of Group 2. As a rule they are not so tough or resistant to shock as alloys of Group 1, but are particularly well adapted for use as the final wear-resisting surface, after the worn part has been built up with high-strength welding rod.

Group 3. Nonferrous Alloys. Cobalt-chromium-tungsten alloys are available in several grades, all highly resistant to wear and corrosion. Differences in strength and toughness make them suitable for a wide range of applications. Many of them retain their original hardness virtually unimpaired at elevated temperatures.

A newer development is the use of nickel-base alloys (Hastelloys) for the facing of parts subjected to severe chemical corrosion. This type of alloy is gaining increased favor in the chemical and process industries, because it combines outstanding resistance to corrosion with excellent mechanical properties; some grades are comparable with high-strength steels in tensile properties. Some grades will also take a high polish and retain it even when subjected to severe atmospheric and chemical corrosion.

Group 4. So-Called "Diamond Substitutes". These are the hardest and most wear-resistant of all hard facing materials. Some are almost pure tungsten carbide; others contain 90 to 95% tungsten carbide with the remainder cobalt, nickel, iron or similar elements. Some materials contain boron compounds or tantalum carbide. The alloying elements are added to impart toughness and impact strength to the tungsten carbides; the hardness, however, is slightly reduced as a result.

* Union Carbide and Carbon Corporation, New York

The diamond substitutes, furnished in the form of small castings, are embedded in the cutting and wearing surfaces of oil-well drilling bits and similar tools. Tungsten carbide inserts are not melted or damaged to any appreciable extent in the usual method of application by the oxyacetylene process. The process of applying tungsten carbide shapes to wearing surfaces is known as "hard setting". After hard setting, the entire wearing surface usually is hard faced, which produces a composite material that has excellent resistance to abrasion with maximum cutting qualities at edges.

Group 5. Crushed Tungsten Carbides of Various Screen Sizes. These are furnished packed in steel tubes, fused to steel strips, or bonded with steel as a composite rod. Both tubes and strips come in short lengths, which are applied like ordinary welding rods. Grains of crushed tungsten carbide are also supplied loose for application with a Haystellite powder dispenser.

Selection of Hard Facing Alloys. The selection of the proper hard facing material for a specific application depends on the factors that cause the deterioration of the wearing part: sliding or rolling friction, shock and impact, heat, and corrosion. Other factors, such as smoothness of the deposit desired, or (in handling sand, rock and gravel) the ability to serve as an efficient digging tool, also influence the choice. When two materials are equally suited, the material of longer life expectancy, although more expensive, will more than justify the greater first cost.

Table I will serve as an approximate guide in the selection of a suitable material.

Hard Facing Procedure. Although hard facing materials can be applied by any standard fusion-welding method, certain factors govern the choice of method for any specific applications: (1) base material to be faced, (2) hard facing material selected, (3) size, shape and thickness of base material and deposited facing material, (4) initial cost of equipment and facing material, (5) smoothness of deposits, (6) over-all cost and (7) quality and appearance of deposits.

Table I. Relative Merits of Hard Facing Materials with Respect to Characteristics of Deposits

(The numbers refer to the five groups listed)

Characteristics of Deposit	Group Number in Order of Preference				
Hardness at atmospheric temperature	4	5	2	3	1
Hardness at elevated temperature	4	5	3	2	1
Resistance to impact	1	2	3	5	4
Resistance to corrosion	3	2	1	4	5
Smoothness of deposit	3	1	2	5	4
Ability to take high finish	3	2	1	4	5
Ability to penetrate (earth-boring or penetrating tools)	4	5	3	2	1
Thinness of deposited layer welding	5	3	2	1	4

Gas Welding. Use of the oxyacetylene blowpipe allows close control of the operation, produces a smooth deposit, ensures easy elimination of particles of scale and foreign matter, and easy forming of edges and corners. Ease of forming is particularly important if grinding of the hard face to close tolerances is required. Other advantages are low loss of expensive alloys by vaporization or spattering, close control of the oxidizing or reducing character of the atmosphere surrounding the molten metal, and more accurate control over the penetration of hard facing alloy into the base metal. This is especially important in the application of certain hard facing materials, some of which should be puddled in, while others are flowed onto the base material by "sweating".

Metal-Arc Welding. The alloy electrode that furnishes the hard facing material is usually coated with flux. The purpose of the coating is to stabilize the arc, to control the melting rate of the electrode, to protect the molten metal from atmospheric contamination and, in some instances, to add alloying elements to the deposit.

Although the process is not so flexible as gas welding, the resultant deposits are of good quality.

Experience has shown that usually, if the area is large, the most efficient method of deposition is to use a weaving-bead type of deposit rather than a straight bead. This requires deposition of a bead ¾ to 2 in. wide. A deposit of uniform thickness with a smooth and regular surface can be obtained readily. Narrow beads are useful for corners, edges and points.

Beading is sometimes used for large areas. For this the beads should be staggered over the entire area and then tied together. This gives an even distribution of heat, minimizes cooling stresses, and usually makes preheating unnecessary, except on round, curved, concave or convex surfaces. The normal thickness of deposit ranges from ⅛ to $\frac{5}{32}$ in., but can be varied in either direction.

The metal-arc welding process is particularly suitable for use on thick base metals where thin, smooth deposits are not required. Another advantage is that only a small amount of distortion is produced in hard facing large steel castings and similar heavy parts because the heat from the arc is localized.

Atomic Hydrogen Arc-Welding. In this process the source of heat is an a-c arc between two tungsten electrodes in a stream of hydrogen. The surrounding envelope of hydrogen protects the electrodes and the base material from oxidation. The arc is defined by a thin brilliant line that forms a loop, under the influence of its own magnetic field and the flowing gas. High-quality deposits are obtained, plus all of the other advantages of the gas process. In addition, a higher rate of deposition may be obtained. The higher initial cost is often offset by the speed and superior results obtained.

Base Materials for Hard Facing. *Medium-Carbon and Low-Carbon Steels.* Carbon steels containing up to 0.50% C can be hard faced with excellent results in nearly all instances. Steels that contain 0.40 to 0.50% C are not only satisfactory for welding, but also possess sufficient strength to withstand severe conditions of service.

High-Carbon Steels. Steels that contain more than 0.50% C can be hard faced if reasonable precautions are taken to prevent cracking. Before hard surfacing, preheating is often desirable and heat treatment, both before and after hard facing, is usually necessary to reduce hardness and brittleness in the base metal.

Low-Alloy Steels. Hard facing alloys can be applied to these steels in much the same manner as to plain carbon steels. Initially, the steel should be in the annealed condition. In a few instances, depending on the composition of the base, heat treatment is required after welding.

High Speed Steels. Hard facing of high speed steels is not generally recommended. Shrinkage cracks and strain checks in many instances render the hard faced piece valueless, regardless of heat treatment.

Stainless Steels. Stainless steels, including the high-chromium steel and the 18-8 Cr-Ni steel, can be hard faced readily if proper preheating and cooling procedures are followed. However, knowledge of the physical properties of the specific type of stainless steel is necessary in order to avoid difficulty from excessive strains, brittleness, or decreased resistance to corrosion.

Manganese Steel (9½ to 14% Mn). These steels can be surfaced by means of a rod that gives an austenitic, work hardening deposit. The electric-arc welding process should always be used, with care to avoid overheating.

Gray Cast Iron. Cast iron can be hard faced, but the method of application differs somewhat from that for steel because of the lower melting point of the cast iron and the surface condition of the iron. Local overheating of the iron must be avoided.

White Cast Iron. Small parts made of white or chilled iron can be hard faced; for larger parts heat treatment is sometimes necessary, taking into consideration the design and location of chills, since preheating may soften some of the chilled areas.

Alloy Cast Irons. The same procedure can be used as for gray cast iron.

Preparation of Metal to be Surfaced. Loose scale, dirt, rust, or other foreign substances should be removed from the area to be hard faced, preferably by grinding or machining. When a file or wire brush is used for cleaning, care should be taken that any scale or other remaining foreign material be floated out during the melting.

When the hard facing material is to be applied in a groove, corner or recess, it is desirable to have all corners well rounded. If only a small area is to be hard faced, a suitable shallow recess or indentation may be prepared for receiving the hard facing metal.

Preheating. In the preheating of parts to be faced, the same general rules should be observed that are applicable to welding. Parts should always be preheated when otherwise the hard facing operation would cause warping or checking, or when time and money can be saved. Steels containing more than 0.40% C should usually be preheated. The optimum temperature for preheating is usually between 700 and 1200 F but may vary with size and composition of the part. For certain classes of electric-arc welding preheating between 350 and 450 F is desirable.

Hard facing of hardened steel is generally unsatisfactory. If a tough grade of hard facing rod must be used and rehardening of the base material is necessary after the hard facing process, oil quenching is recommended; water quenching is seldom used.

Fluxes. In the gas and atomic hydrogen welding processes, fluxes are essential only in special instances. Sometimes a flux may help if a second hard facing layer is necessary, or if removal of scale and oxide from the base metal is desirable. This is especially true with cast iron. The principal advantage of a flux is that, by floating on the molten puddle of deposited material, it smoothes the surface, retards the cooling, and protects against oxidation. A denser, harder deposit of superior microstructure is produced if a flux is used. In shielded electric-arc welding, the flux processed on the electrode itself is sufficient.

Thickness of Hard Facing Deposit. The proper thickness of deposit depends on the specific application, but usually ranges from $\frac{1}{16}$ to ¼ in.; the average is approximately ⅛ in. Usually, however, a part that requires a deposit thicker than ¼ in. should be rebuilt, before hard facing, to within $\frac{1}{16}$ to ¼ in. of the finished size. For this purpose an alloy of Group 1 should be used, or material similar to the base metal. The final hard facing deposit is applied thick enough for grinding to finished size.

Hard Facing of Steel. *Group 1. Ferrous. Less Than 20% Alloying Element.* For applying rods of Group 1 to steel, a flame containing a slight excess of acetylene should be used, since a neutral flame may cause boiling. Penetration into the base metal should be less than $\frac{1}{32}$ in., depending on the type of rod used. Some of these materials are work hardening, and light peening is recommended, especially on large areas, to harden the surface and lessen danger of shrinkage cracks.

In gas welding, the hardness of hard facing deposits of Group 1 depends largely on the amount of acetylene in the flame and on the rate of cooling. A small excess of acetylene is usually necessary to prevent boiling of the fused metal. A much greater excess can be used if an exceptionally hard deposit is desired. In general, the greater the excess of acetylene and the slower the cooling rate, the harder the deposit. A quenched deposit is not so hard as slowly cooled metal, but is tougher.

For electric-arc welding, electrodes are available that give a medium-carbon alloy steel facing. In using most of such electrodes the rod should be positive and the work negative. The welding current should be adjusted to give flat beads such as are generally obtained with high currents, and the deposit should be made with a weaving motion. For this class of work, welding should be done in a horizontal position only.

Group 2. Ferrous. 20 to 50% Alloying Elements. Alloys of this group are applied to steel by thorough amalgamation. To assure successful hard facing, the base metal should actually be melted; "sweating" is not sufficient. In gas welding, a neutral or slightly carburizing flame is generally used. Since the significant physical properties of these alloys are virtually unchanged within a range of carbon content from 2 to 4%, penetration of the base metal has no marked detrimental effect on the quality of the deposit.

For electric-arc welding, electrodes are available that will produce a hard steel facing that cannot be machined unless annealed. For most of such electrodes the rod should be positive and the base metal negative. Wide or narrow beads can be used as desired. Each bead should be brushed thoroughly before the next is deposited. In some instances peening of the completed bead will harden the deposit. Quenching in cool water will increase the surface hardness of some alloys. For best results the piece being faced should be in a horizontal position.

Group 3. Nonferrous Alloys. These alloys should be applied with minimum penetration into the steel base. In this manner, dilution with iron from the base is avoided. Thus the hardness at high temperatures and the resistance of the alloys to abrasion and corrosion, are not reduced. For the cobalt-chromium-tungsten alloys, the flame for gas welding must contain an excess of acetylene and should be adjusted so that the outer cone, denoting excess of acetylene, extends double the length of the inner cone. This excess of acetylene will "sweat" the surface of the steel base and allow free spreading of the hard facing metal without any stirring or agitation of the puddle. When Hastelloy facing is selected for resistance to corrosion, a neutral flame is desired to avoid carburization, which reduces such resistance.

A small area of the surface to be hard faced should be brought to a sweating temperature, and the end of the rod should be allowed to melt in the flame and spread evenly over the sweating area. The hard facing material, when applied at the proper temperature, wets the base metal and spreads ahead readily in the flame, while the base metal is brought to the sweating temperature just in front of the puddle. The rod should not be stirred or puddled. The alloy is spread by the welding flame.

It is preferable to deposit the coating to the desired thickness in one operation. A flux is usually unnecessary if the steel base is clean. The alloys in this group can be applied by the metal-arc process with either bare or flux-coated electrodes, preferably coated. Reverse polarity is always used; the rod is positive and the steel base negative.

Group 4. Tungsten Carbide Inserts. Tungsten carbide inserts are now very widely used for hard setting oil-well drilling tools. The size and spacing of the inserts vary with the type of tool. The procedure involves cutting grooves in the steel base metal with either an oxyacetylene cutting blowpipe or a grinding wheel. In setting an insert, the steel in a groove should be melted with an excess-acetylene flame and the insert should be picked up with the heated end of a high-strength steel welding rod and partially submerged in the molten puddle. Finally the insert should be completely covered with steel supplied by the welding rod. This operation is repeated until the desired number of inserts has been set. Maximum resistance to wear is obtained when a final coating of hard facing alloy from Group 5 is deposited over the inserts.

Group 5. Crushed Tungsten Carbide with Steel Binder. Both types of these materials—composite and tube—are applied in much the same manner. The operation should be performed with an oxyacetylene flame that contains a small excess of acetylene. The penetration into the base should not be so deep as in ordinary steel welding, but some stirring with the rod is necessary in order to obtain an even distribution of the deposited metal. These rods are not free-flowing because of the presence of the tungsten carbide particles, which do not melt. The deposit should not be kept molten for too long. The welding tip should be large enough to produce a flame that will supply the required amount of heat at a pressure low enough not to blow the molten metal.

Hard Facing of Cast Iron. *Group 1.* In general, the hard facing of cast iron with the materials of Group 1 is similar to the treatment of steel. However, it is best to heat a small area at a time with the blowpipe and to break the surface crust as it forms, with the end of the rod. A little puddling is usually necessary and a good flux is often helpful. Because of the low melting point of cast iron, considerable care should be taken when working on thin surfaces, edges, and corners.

Group 2. These alloys are applied to cast iron in essentially the same manner as they are applied to steel.

Group 3. In applying these alloys by gas welding, a little less acetylene is used in the flame than for steel. Since alloys of Group 3 do not flow so readily on cast iron, it is advisable to break the surface crust with the end of the rod. A cast-iron welding flux is often helpful. It is usually best to apply an initial thin coating and then go over it again and build it up to the desired thickness. Since these alloys have a higher melting point than cast iron, care must be taken not to melt the base metal too deeply. It will be advisable to back thin sections with wet asbestos or carbon paste.

Groups 4 and 5. Materials of these groups are rarely, if ever, applied to cast iron. When they are, the application is along the same lines as for steel.

Cooling Procedure. Parts hard faced by the oxyacetylene process should preferably be cooled slowly to minimize residual stresses in the deposited metal. Somewhat less care is necessary when the base metal and welding rod are of the same composition. If no further heat treatment is necessary, the hard faced piece may be cooled under the torch, or in dry lime, sand or other packing material. However, if the piece is to be heat treated in order to refine the grain and to improve the strength of the base metal, the hard faced piece should be heated and then quenched in oil (seldom water) or normalized by cooling in air.

Finishing the Hard Faced Deposit. *Groups 1 and 2.* Some shaping of these hard facing materials can be done while they are in a plastic state. If heated with the blowpipe to within about 300 F of the melting point, the deposit can be scraped off in thin layers with an implement, such as an old file, until reduced to the required size and shape. Ordinarily, alloys of Groups 1 and 2 are machined with difficulty. If they cannot be brought down to exact final dimensions by "hot filing", grinding is necessary.

Group 3. Most grades of the nonferrous hard facing materials are not machined readily, but can be finished easily by grinding. The wheel speed should not be less than 2800 nor more than 4800 surface fpm. Grinding checks may result from higher speeds or the use of wheels that are too hard.

Groups 4 and 5. In grinding parts hard faced with these materials, the best results require the use of wheels designed for this particular work.

Bond Between Hard Facing Material and Base Metal. The bond between the hard facing and the base is as strong and sometimes stronger than the hard facing deposit. Naturally, alloys that are puddled into the base metal form a good strong bond. Even the alloys that are merely sweated to the base, form a bond that is stronger than the hard facing metal itself. If properly applied, a hard facing metal does not break away from the base through the bond.

In many instances, surface cracks are not detrimental since they usually extend only through the deposited metal and not into the base. Undesirable surface cracks can sometimes be repaired if the metal adjacent to the crack is heated to a red heat, then melted down into the bottom of the crack and allowed to close in slowly, with a few more drops added from the welding rod. Precautions should be taken to ensure very slow cooling.

Jigs for Hard Facing. Many operations are facilitated by the use of special jigs or fixtures. Some operations are practicable only through the use of such auxiliary appliances. Several typical examples are as follows:

It has been found much easier and faster to hard face undercutter bits for coal mining when they are set up on a jig. Either a "merry-go-round" jig or a moving table is employed to good advantage, as evidenced by a record of 450 bits hard faced by one operator in one hour.

With the aid of a jig, a plowshare can be hard faced and the nose of it shaped in one operation. By the use of another device, the share can be turned completely over and the work adjusted so that the working surface is always level. Rotating jigs or chucks are a great aid in hard facing steam valves, dies, automotive valves and valve seat inserts, and other small parts.

The Pickling of Iron and Steel Products

By C. H. McCollam* and D. L. Warrick*

PICKLING is the term applied to the chemical removal of surface oxides from metal by immersion in an acid solution. Wide variations are possible in the type, strength and temperature of the acid solutions used. The procedure depends on the material to be pickled, the character of the scale involved and the surface desired after pickling. The following discussion will deal only with the pickling of ferrous metals.

The pickling of hot rolled, low-carbon steel is typical of the basic principle involved. In this instance the surface oxide to be removed is mill scale, formed at comparatively low temperatures during or after hot rolling. Removal of such scale is one of the simplest of the cleaning problems. The steel is submerged in dilute sulfuric acid until free from scale, and then is removed and rinsed. For purposes of economy and efficiency the acid concentration is held at approximately 10% and the temperature is maintained between 150 and 190 F.

A container is required in which the acid and the material to be pickled can be held for a reasonable time at the desired temperature. To this basic piece of equipment, operating conveniences have been added such as cranes, mechanical agitators and instruments for control of temperature. The pickling tub or tank is subject to changes in construction, which will be discussed further in another part of this article, as will pickling acids, inhibitors, foam-producing agents, and rinses.

Pickling Procedures for Various Ferrous Metal Products. Although pickling appears to be a simple process, modifications are necessary in many instances. Because of the broad influence of sometimes obscure variables in scale formation, and because of the difference in processing practice and equipment encountered even in two plants that make the same product, it is not practicable to reduce pickling procedure to a standard formula. In certain instances, the problem has become so complicated that even the mechanism of scale removal by pickling has become a controversial subject. Therefore, the procedures described in the following paragraphs are merely the methods that have been successful in plants producing the particular material under discussion, rather than formulas that can be followed without modification.

Cleaning, before pickling, is often as important as the operation itself. The iron or steel is frequently covered with grease from previous fabricating processes. This grease is not soluble in acid and renders pickling difficult. Hot alkaline solutions are generally satisfactory for cleaning such material, but their use should always be followed by careful rinsing before the material is placed in the acid. Another cleaning method requires heating the metal to a moderately high temperature for a short time to remove the grease.

When low-carbon steel is pickled for enameling, galvanizing or tinning, special precautions are necessary to ensure a surface that is chemically clean as well as free from scale. In such instances a slightly but definitely etched surface is often considered an advantage, permitting greater adherence of the coating to the metal. In pickling low-carbon steel, inhibitors or foaming agents may be used in the bath, but only with careful selection and proper precaution, because some inhibitors leave a thin but very tightly adherent surface film, which clings persistently to the metal even after careful rinsing.

The trend in recent years toward lower pickling temperatures, about 150 to 160 F, has resulted in economy in steam consumption and in better quality of the finished product. Where time and pickling capacity permit, an acid concentration of 5 or 6% is advisable. However, where comparatively low temperatures are employed, it is customary to compensate for decreased thermal activity by raising the acid concentration to about 10 or 15%.

In the continuous production of sheet or strip steel, provision is usually made for continuous pickling so that fabrication can proceed without interruption. In this continuous system, control of the rate of pickling is accomplished by varying the temperature or the acid content of the bath, or both. Close supervision is necessary if efficiency and economy are to be realized, since the acid content of the bath is constantly changing. Acid concentration and temperature are frequently kept too high for best results in economy or quality, so that the operation may be completed in the time allowed.

In pickling for galvanizing or tinning, many plants use two pickling baths: first a 5 to 10% solution of sulfuric acid in water at 150 to 190 F, and second, a short dip in cold concentrated muriatic acid (18 to 20 Bé) or in a moderately strong solution of muriatic acid at a somewhat elevated temperature. The use of high temperatures with muriatic acid is wasteful because this acid has a strong tendency to evaporate, filling the atmosphere with noxious fumes.

Vigorous mechanical agitation of the bath is always advisable. When the solution is allowed to remain stagnant, gas pockets may form, keeping the acid out of contact with the metal and arresting the pickling action on these localized areas. When the steel is galvanized, these scale-retaining areas remain uncoated. Agitation offers the further advantage of securing uniform acid concentration throughout the bath, assuring a more nearly uniform rate of pickling.

When sheets have been pickled for galvanizing or tinning, as short a time as possible should elapse between

*The Timken Roller Bearing Company, Canton, Ohio.
* Deceased

pickling, rinsing and coating operations. If a delay occurs between rinsing and coating, the material should be stored under water and never allowed to dry. Contact of the moist iron with air will cause rusting. Furthermore, any ferrous salts from the pickling bath that dry on the work, become oxidized and difficult to remove.

When pipe or seamless tubing is to be pickled, particularly pieces of small inside diameter, high acid concentration is advisable, since the acid solution that first enters the tube must often complete the pickling of the inside surface. Lifting the bundle above the bath occasionally, to drain the spent acid out of the tubes, helps to overcome this difficulty. Jets of air or steam that direct a current of pickling solution through the tubes are sometimes a valuable aid. Mechanical rockers may also be used to advantage in removing thick or tight scale.

Heat treated material introduces many special pickling problems. It has been demonstrated that when alloy steels are heated above a certain temperature, which varies with the type of steel, an electrolytic action is set up between the scale and steel during pickling. This action proceeds at the expense of the clean metal and results in serious pitting of the surface. Inhibitors have been found to be of little value in preventing such pitting. Scale formed during normalizing represents the worst condition as far as pickling time and pickle pitting are concerned; scale formed during tempering is the easiest to remove. Best results will usually be secured by using a fresh bath of 5 to 10% sulfuric acid (inhibited) with temperature between 145 and 155 F, and with provision for mechanical agitation.

Scale formed during forging is difficult to remove. Formed at elevated temperature, this scale is likely to be thick, glassy and extremely adherent. Also such scale is likely to be knocked off during handling, leaving small exposed areas of metal. At such places deep pickle pitting is likely to occur. However, when the scale is removed from large areas of metal before pickling, the pitting is much less severe. Pitting is decreased by the mechanical removal of as much of the scale as possible either before or during pickling. Good results have been obtained by pickling in 8 to 15% sulfuric acid, at 150 to 160 F.

Pickling Stainless Steels. Stainless steels present a special pickling problem because scale containing high percentages of chromium oxides is not readily attacked by sulfuric acid alone. A common practice for stainless steels is to employ a mixture of about 10% sulfuric acid with 2 to 10% muriatic acid or a mixture of 10% sulfuric acid with about 10% of common salt. In the latter instance, muriatic acid is generated by reaction between the sulfuric acid and the salt. Muriatic acid alone is sometimes used. For stainless steels, the pickling is followed by a bright dip in 5 to 50% nitric acid by volume. The more dilute solutions of this acid are generally used warm but the higher concentrations should be used cold, because high concentrations of nitric acid are detrimental to many materials used in constructing pickle tubs. Thorough rinsing in hot water is essential for best results. Scrubbing is sometimes done simultaneously.

Equipment. The pickling tank may be constructed of wood, steel, brick, concrete, lead, monel metal or stainless steel. Steel and concrete tanks are generally lined with some acid-resisting material, while wood, brick or alloy tanks are either lined or unlined, depending on the service for which they are intended and on the cost.

Wooden tanks are the cheapest to construct. They are generally made from cypress or long-leaved yellow pine. A lining of asphaltic material is often used between the walls. Tubs may be made of common or acidproof brick, with or without mastic lining material between courses. Rubber linings may be used in tanks of wood or steel. Monel metal and stainless steel offer many advantages but the cost is generally prohibitive. Steel tanks, sheathed in brick and lined with rubber, are satisfactory for most uses.

Storage Tanks for Acid. Muriatic acid can be stored in rubber-lined steel tanks or in tanks lined with wood that has been impregnated with certain waxes. Hydrofluoric acid is generally stored in lead-lined tanks.

Acid lines carrying concentrated sulfuric acid of 58 Bé or higher from the storage tank to the pickle tub, may be of iron pipe with iron fittings. Care should be taken to calk all the joints with a good acid-resisting material. Sections of pipe that are immersed in the pickling bath should be made of lead, copper or bronze. Heavy rubber hose is sometimes employed. Stainless steel lines are satisfactory for use in strong nitric acid.

When copper or bronze is used in connection with equipment for pickling, there is always the possibility of electrolytic deposition of copper on the pickled surface. Ordinarily this is of no consequence, but if the stock is to be carburized without machining after pickling, the copper film will prevent carburization. Also copper stains on full-finished sheets are objectionable. Copper or bronze should not be used in the pickling tub in such instances.

Drainage lines should be made of vitrified tile carefully calked with an acidproof cement to avoid leakage, and should be large enough to provide adequate drainage at all times. A wooden lattice, preferably of cypress, should cover the floors around the pickle tubs.

Agitation. This practice saves time, metal, and acid. Air, steam, or mechanical movement of the tub or charge may be used; each has certain advantages. In some plants the tub is mounted on rockers; in others the charge is supported on chains or saddles of acid-resistant metal, which impart a continuous or intermittent motion to the work. Another system involves the use of a large plunger, which alternately raises and lowers the level of the liquid in the tub. Small articles may be pickled in a tumbling barrel. No definite recommendation can be given, because the means of securing agitation in the tub will depend on the size and kind of material being treated, the equipment available, and the result to be secured. Each installation presents an individual problem.

Adequate Ventilation. This safeguard should be provided for when the pickling room is designed. Good ventilation should be maintained at all times. Ventilating equipment should be of acidproof material.

Pickling Solutions. Sulfuric, muriatic, nitric, and hydrofluoric acids, or mixtures of these, are generally used. Sulfuric acid is the cheapest pickling acid and the one most commonly employed. Muriatic acid is used for special purposes, such as etching before galvanizing or tinning, and sometimes for pickling stainless steel. Nitric acid is used in the pickling of stainless steels and is occasionally employed to oxidize scaled surfaces in order to facilitate pickling. Hydrofluoric acid is sometimes added to the bath to accelerate pickling, and is used occasionally in pickling castings to remove sand.

Concentration of Acid. The action of the pickling solution on the metal is in approximately direct proportion to the acid concentration up to about 25% acid by weight. The concentration used depends on the kind and temperature of acid, the type of material being pickled, and the surface desired. Thus when sulfuric acid is used on mild or pearlitic alloy steels, the maximum concentration is 20 to 25% and the optimum is 8 to 10%. For the pickling of tubes and pipe a high acid content should be maintained because the solution on the inside of the tube does not circulate, and consequently becomes depleted before the scale has been removed if weak acid is used. Muriatic acid solution is maintained between 5 and 50% by volume. The higher concentrations of this acid cause definite etching of the surface. Nitric acid is used in amounts from 5 to 50% by volume. Concentrated solutions of nitric acid have a passivating effect on steel surfaces. The fumes from nitric acid are dangerous and adequate ventilation should be provided.

Testing of Pickling Solutions. This important part of pickling supervision is frequently overlooked. The solution in pickle tanks should be sampled regularly. In the pickling of sheets, the acid strength should be determined after each lift in batch pickling, and every 30 min in continuous pickling. For testing the acid and iron contents of the pickling bath a sample can be titrated with standard solutions. The use of a hydrometer for checking pickling solutions is not recommended, because of varia-

tions in gravity introduced by the ferrous sulfate content. The following procedures can be used for titrating pickling solutions.

Determination of Sulfuric Acid Content. Five milliliters of pickling solution is measured into a 200-ml flask. Then 25 ml of water and 2 drops of methyl orange solution are added. Standard sodium carbonate solution is added until the last drop causes the color of the pickling solution to change from red to yellow. Each 5 ml of the sodium carbonate solution equals 1% of sulfuric acid in the pickling tank. (This simple relation, sufficiently accurate for commercial purposes, is based on the specific gravity of 10% sulfuric acid.)

The standard sodium carbonate solution may be made by dissolving 11.52 g of dried cp sodium carbonate in 1000 ml of distilled water. (This standard solution is slightly stronger than N/5 sodium carbonate solution, which may be substituted without appreciable error in commercial practice.)

Methyl orange solution may be made by adding 1 g of methyl orange powder to 1000 ml of distilled water. This solution should be kept in a dropping bottle.

When the pickling solution is muriatic acid, the determination may be carried out in exactly the same manner as outlined above for sulfuric acid, except that, in the final calculation, each 5 ml of the standard sodium carbonate solution equals 2.07% by volume of 20 Bé muriatic acid, or 2.36% by volume of 18 Bé acid. Each of these values is equivalent to 0.755% by weight of hydrogen chloride (based on the specific gravity of 10% hydrochloric acid solution).

Determination of Iron Content. Five milliliters of pickling solution is placed in a 200-ml flask and diluted with 5 ml of water. Standard potassium permanganate is added from a burette until the last drop turns the pickling solution pink. Each 5 ml of standard permanganate solution equals 1% Fe or 5% $FeSO_4$. The pink color of the end point fades quickly when organic inhibitors are present; therefore, the titration should be carried to completion as rapidly as possible.

The standard potassium permanganate solution can be made by dissolving 6.01 g of cp potassium permanganate in 1000 ml of distilled water. (This standard solution is slightly weaker than N/5 potassium permanganate, which may be substituted without appreciable error in commercial practice.)

Addition of Acid. At all times the acid content should be maintained above the minimum found to be practicable for the material being pickled. For mild carbon steel and most alloy steels requiring a sulfuric acid solution, about 5% acid is a desirable concentration. Acid should be added frequently and in small amounts to keep the bath uniform. When acid is being added, the bath should always be agitated to assure thorough mixing.

If consumption of acid is to be established accurately, many factors must be considered. The acid that is added must be carefully measured, either by metering or by means of a measuring tank. When additions are recorded in terms of so many "minutes of acid" through a pipe, variations generally result from the amount of acid in the tank, the air pressure on the acid line and other factors. Variation in the size and shape of the material being pickled, has considerable influence on consumption of acid.

Changing of Pickle Solutions. It is well known that ferrous sulfate has a damping effect on the efficiency of a pickling bath. The ferrous sulfate content of a bath is five times the iron content; and it has been demonstrated that with 40% ferrous sulfate (8% Fe) the rate of attack of sulfuric acid on steel is reduced 50%. It is common practice to let the ferrous sulfate content reach 25% (5% Fe), then to use the solution until the acid content has been reduced to less than 5%, and dump the tub.

Disposal of Waste Liquor. The practice of dumping waste pickling solutions into sewers and streams has resulted in dangerous pollution of water. Laws in many states require the neutralization of pickling acid before disposal.

In connection with large pickling installations, plants may be installed for recovery of acid and salvage of iron compounds. Such plants are expensive to build and maintain and their application is limited. In smaller pickling plants, it is more economical to kill the spent acid with lime in settling basins.

Pickling Temperatures. Pickling tanks are heated ordinarily by the introduction of live steam through an open or perforated lead pipe. Temperatures can be checked at intervals by an ordinary thermometer, or indicating or recording instruments can be installed for this purpose. Temperature controls are available for installations where temperature variation must be held to a minimum.

The Effect of Temperature. An increase in temperature greatly increases the activity of the pickling bath. Sulfuric acid at 190 F has more than 100 times the solution rate of the same acid at room temperature. Overpickling is likely to occur at high temperatures. The choice of an inhibitor is an important factor in establishing the limiting temperature, since some inhibitors fail rapidly at high pickling temperatures.

Although a temperature of 170 to 190 F is sometimes satisfactory when the time cycle is short, pitting may result if the pickling period is prolonged. With many high-carbon and alloy steels, a pickling temperature of 140 to 150 F has been found satisfactory for efficiency, surface quality, and life of the inhibitor.

Pickling Inhibitors. Pickling inhibitors are agents that may be added to an acid pickling bath to diminish the attack of the acid on the metal areas from which the scale has been removed, without appreciably retarding the rate at which the acid removes scale or rust; and to diminish the severity of hydrogen embrittlement.

Theory and Mechanism of Inhibitors. The actual mechanism of inhibitor action is not well understood. Some investigators believe that inhibitors are negative catalysts that are selective in action, retarding the reaction of acid on metal but not on scale. In practice, no inhibitor continues its original effectiveness unabated throughout the entire pickling cycle. However, inhibitors lose efficiency so slowly that the loss can hardly be attributed to reactions in which the inhibitor plays a major part as reagent. The effect seems analogous to the familiar poisoning of a catalyst.

Various observers have stated that inhibitor action seems to be associated with an increase in the hydrogen overvoltage at the metal (cathode) surface. A protective coating of hydrogen, maintained on the metal surface, helps to protect the metal from direct contact with the acid, thus diminishing the attack.

Another theory is that a thin layer of inhibitor material is adsorbed or plated out on the surface of the metal. Many of the known organic inhibitor solutions are colloidal in nature, a fact that lends support to the possibility of either adsorption or cataphoric migration of inhibitor particles. However, if such a layer exists, it is so extremely thin as to escape detection in many instances.

Nature and Composition of Inhibitors. Widely varied materials have been advocated and used as inhibitors, from cabbage leaves or wheat bran to complex synthetic organic chemicals. In numerous instances raw materials and by-products have been found useful as inhibitors, and many are still being used without the separation or identification of the active ingredient. A comprehensive list of such materials would be difficult to prepare but would include the following: sludge acid from oil refineries, waste animal materials, waste sulfite cellulose liquor, wheat bran or off-grade flour, sulfonation products of such materials as wood tar, coal tar, and asphaltum. These materials, varying widely in their effectiveness and uniformity, have an economic advantage and are not necessarily inferior to synthetic inhibitors.

A wide range of synthetic chemicals has been reported as showing inhibitive properties. Many of these are extremely complex in structure and high in molecular weight. Aldehydes, thioaldehydes, mercaptans and other sulfur-containing organic compounds, as well as organic nitrogen bases and their derivatives, seem to be favorites, particularly those in which the nitrogen is linked within a heterocyclic ring, such as pyridine and quinidine. The cost of synthetic inhibitors often precludes their use for production work. However, some of these compounds are so efficient that extremely small amounts are required.

Foaming Agents. The function of foaming agents is to blanket the surface of the pickling solution with a suds, which traps and holds any fine spray of acid that would otherwise be carried into the atmosphere with the evolved hydrogen gas. The chief advantage of foaming agents lies in their ability to prevent the pollution of the atmosphere by acid fumes.

Confusion still exists in the minds of many, concerning the relation between inhibitors and foaming agents. Actually they represent independent phenomena, although in many preparations they are coexistent. When a sufficient quantity of a good inhibitor is used, the evolution of hydrogen gas is so small that a foaming agent becomes virtually unnecessary.

Methods of Testing Inhibitors. Because of the wide variety of inhibitors and their diversity of behavior, it is important to have some method of testing their efficiency. The ultimate test is their behavior in the pickling bath, but laboratory tests offer a convenient means of comparing the value of inhibitors under carefully controlled conditions.

Laboratory tests for inhibitors are of two general types: (1) tests that measure the loss in weight of metal in inhibited acid, and (2) tests that measure the amount of hydrogen evolved. The latter tests depend on the fact that when metal reacts with a nonoxidizing acid, hydrogen is evolved; but when the acid reacts with metallic oxide, water is formed with no evolution of gas. Hence a theoretically perfect inhibitor should allow removal of the scale with no evolution of hydrogen.

Inhibitors frequently fail in service because of localized overheating at the point where steam is introduced into the bath. Laboratory tests should take this fact into consideration. A satisfactory check may be made by refluxing a sample of the inhibited pickling solution for not less than one hour. Because of the wide difference in the solubilities of high-carbon and low-carbon steels in acid, tests for efficiency of inhibitors should be made on the same grade of steel as will be treated in the pickle tub.

Advantages of Inhibiting the Acid.

1 Reduction in metal loss
2 Saving of pickling acid
3 Prevention or minimizing of scrap losses from overpickling
4 Decrease in blistering and in hydrogen embrittlement

Disadvantages of Inhibiting the Acid.

1 Increased pickling time
2 Possibility of residual surface film, which may interfere with subsequent operations
3 Added cost of inhibitor

Washing and Liming After Pickling. The importance of a clean rinse tub is not always appreciated. Ferrous sulfate gradually accumulates in the rinse water. Traces of ferrous sulfate that remain on the steel after rinsing will oxidize while drying, leaving a film of rust on the surface. Acid also may accumulate in the rinse tub and promote rusting of the steel when exposed to the air.

Even with thorough rinsing in clean tubs, it is difficult to remove the last traces of acid with water alone. When pickled steel must be protected from rust, an alkaline rinse is advisable to remove the last traces of acid. An effective solution may be made of ½% of caustic soda and ¾% of trisodium phosphate ($Na_3PO_4 \cdot 12H_2O$) in hot water. The alkalinity of the bath should be checked frequently and maintained by the addition of caustic soda. Acid titration (methyl orange indicator) is the best means of determining the alkalinity. Five milliliters of the above alkaline solution should require 5 to 10 ml of N/10 sulfuric or hydrochloric acid for neutralization.

A cold dip in milk of lime is also effective for neutralizing traces of acid. This method leaves a coating of lime, which is not easily removed from the surface. If cold drawing operations follow pickling, the lime will serve advantageously as a lubricating agent.

The presence of a white suspension of solid material is not proof that sufficient lime remains in the solution. Calcium sulfate, formed when lime reacts with sulfuric acid, is a white powder only slightly soluble in water, and may easily be confused with lime. Titration of the available alkali with a mineral acid gives a positive index of the lime content of the solution.

Pickling Defects. Pickling is frequently blamed for certain defects that appear during the pickling operation but that have their inception elsewhere. The tendency is to blame all failures on overpickling or to condemn the steel as defective. Certain defects, however, come from neither of these causes, but are the result of earlier operations, such as rolling, heat treating, or forging.

Overpickling. This error causes porosity of the transverse surfaces and a roughening of the whole surface, accompanied by discoloration and decrease in size and weight. Overpickling can be avoided by removing the material from the bath promptly when the pickling has been accomplished. Inhibitors aid in preventing overpickling, but are not a complete guarantee that it will not occur.

Pickle Pitting. This defect may be classified into several different types, according to cause. Three of these types are common enough to justify special consideration.

Electrolytic pitting is by far the most prevalent and troublesome type, particularly on heat treated alloy steels and forgings. It is characterized by a patchwork of pitted areas irregular in shape; the depth is indirectly proportional to the area. Caused by an electrical potential between the scaled areas and the clean steel, electrolytic pitting occurs only where the scale has been removed from small areas before the pickling, or at an early stage in the process. It should be noted that the pitted areas are often longitudinally aligned and that the boundaries are usually rather sharply defined or channeled, probably because maximum potential exists at such locations. When inhibited acid is used, the pitted area is generally uniform in depth, with a channeled boundary; uninhibited acid makes the pitted area irregular in depth.

Although severe pitting is rare, it may be caused by overpickling, particularly in inhibited acid. This serious defect indicates carelessness on the part of the pickler, because such pitting appears only when material is allowed to remain in the bath much longer than is necessary for complete removal of scale.

Pits that have been caused by rolled-in scale or refractories in the rolling process, are intensified during pickling.

Nonmetallic inclusions, segregated carbides, or surface strains are frequently held responsible for pickle pitting. These factors may have some influence but their importance has been overstressed. It is always advisable first to investigate the more frequent causes discussed in the preceding paragraphs.

Blistering. This is a troublesome defect on sheet and strip steel. Of the several theories concerning the origin of blisters, the most reasonable seems to be that gaseous inclusions cause these flaws in the steel by forming gas pockets just beneath the surface during rolling. Hydrogen generated in the pickling operation, penetrates these pockets and lifts the surface, causing a blister. Properly selected inhibitors may minimize blistering, but it is doubtful that they can prevent it entirely.

Hydrogen Embrittlement. This phenomenon gives some trouble when cold working operations follow too soon after pickling. Hydrogen embrittlement seems to result from the penetration of the steel by nascent hydrogen. This type of embrittlement is not permanent and may be eliminated by aging or, more rapidly, by soaking the steel in boiling water. Inhibitors are valuable in minimizing this effect.

Safety. When strong acids and alkali are splashed or spilled, they cause severe burns if not neutralized promptly, and are destructive to clothing. A supply of cold running water should be available at all times for washing. It is important that large amounts of water be used, for when small amounts of water are added to concentrated sulfuric acid, heat is generated, which may add to the severity of the burn. Safety showers are recommended for providing the necessary volume of water in such an emergency.

To remove the last traces of acid from the skin, after thorough rinsing with cold water, sodium bicarbonate or baking soda may be used either dry or mixed with water.

Ammonia may be applied to clothing, but should not come in contact with the skin. In severe injury, consult the medical department for further treatment.

To remove traces of alkali left after washing with cold water, powdered boric acid may be used, or a saturated solution of boric acid in water. A physician should be consulted for further treatment.

Hydrofluoric acid burns are exceedingly severe and painful. Hence, when this acid must be handled, the utmost care should be taken to prevent any contact whatsoever with the skin. Material being pickled in hydrofluoric acid should never be handled without rubber gloves.

The Electrolytic Pickling of Iron and Steel

By Walter R. Meyer*

ELECTROLYTIC pickling of iron and steel is employed to escape some of the difficulties encountered in still pickling. The removal of rust as Fe_2O_3 is comparatively easy with still pickling methods, but the removal of the black magnetic oxide of iron, Fe_3O_4, which is slowly soluble in sulfuric acid, is difficult without the use of electrolytic methods. Before discussing specific processes, some general problems will be considered, such as the nature of scale and its removal, and hydrogen embrittlement.

The Nature of Fire Scale and Its Removal. The black oxidation product of iron, commonly called "fire scale" or "hammer scale", which forms during the heat treatment of iron or steel, is composed of FeO, Fe_3O_4, and a top layer of Fe_2O_3. The chemical composition of fire scale on hot rolled stock and heat treated parts may vary considerably, but the important point is that the composition of the scale varies from ferrous oxide at the metal interface to magnetic oxide with a thin layer of ferric oxide at the surface. Hering has found that the magnetic oxide is attacked only slightly by sulfuric acid, but that hydrogen, formed either electrolytically or by the attack of acid on the iron, leads to rapid dissolution of the scale. The probable mechanism of removal of fire scale is an acid attack on the ferrous and ferric oxides; partial reduction of the magnetic oxide and the dissolution of the reduction products; the reduction resulting from the electrolytically formed hydrogen, or, in still pickling, by the action of the acid on the iron; and a resultant undermining of the residual scale with some mechanical lifting action provided by the discharged hydrogen.

Advantages of Electrolytic Pickling Over Still Pickling. Electrolytic pickling is usually much more rapid than still pickling because of the greater evolution of hydrogen during electrolytic pickling, which agitates the pickling solution, reduces scale, and tends to pry off scale from the surface of the steel. In acid consumption, however, there is little difference between electrolytic pickling and inhibited acid pickling. Absorption of hydrogen, which may lead to embrittlement, occurs in both electrolytic pickling and still pickling. The effects of absorbed hydrogen can be removed by baking the work material for about one hour at 300 F, or a shorter time at higher temperature.

The Bullard-Dunn Descaling Process. This process is used extensively because it removes scale quickly from heat treated parts, without affecting the base steel. The process can be employed for large parts hung on racks and also for bulk parts contained in special tumbling baskets. The steel is first cleaned of oil and grease electrolytically by making it either anodic or cathodic in special alkaline cleaners. Anodic cleaning is usually preferred because this cleaner is used for stripping tin deposited in the process, and soon becomes contaminated with tin that would plate out if cathodic cleaning were used. The work is then made the cathode in a solution containing 10% by volume of 66 Bé sulfuric acid, at 140 to 150 F. Current densities from 60 to 75 amp per sq ft are recommended. The bath contains about one gram per liter of tin and, when the scale has been removed, the tin is deposited on the clean steel in a uniform coating, which prevents further attack by the acid. Silicon-iron anodes are used and a special surface-active material is added to the acid solution to produce a light foam that minimizes fuming and insures the formation of a smooth continuous coating of tin. Frequently, the tin coating is left on the work to afford some protection against subsequent rusting; however, the coating can be removed quickly by making the work material anodic in the alkaline cleaner that is used for degreasing.

The Madsenell Process. This process employs anodic electropickling to remove carbon smut and absorbed gases, notably hydrogen, from ferrous metal in order to obtain an excellent surface for adhesion of electrodeposits or hot dipped coatings. The work is first cleaned and pickled, either by still or electrolytic methods, and is then transferred to the "degassing" bath. The electrolyte is sulfuric acid of concentration greater than 85% maintained between room temperature and 100 F. The work material is made the anode with the current on when immersed. A 12-v line is usually employed, which provides a current density of 50 amp per sq ft initially, but which drops, within 30 sec to 10 min, to almost zero current with resultant cessation of the gas evolution.

This process removes some of the effects of the pickling of the fire scale rather than being a method designed for the removal of scale. Some possible disadvantages may be the necessity of maintaining a high acid concentration in the bath, the need of direct-current generators or rectifiers, and the maintenance of good electrical contact.

The Hanson-Van Winkle-Munning Electrolytic Bright Dip. This process comprises two steps. First, the work is made the cathode in a warm dilute sulfuric acid bath, 10 to 20% acid, at a current density of from 10 to 150 amp per sq ft for several minutes. The scale is removed effectively but the work may be coated with an "acid black". To remove this smut, the work is rinsed and transferred to a stronger acid bath (40 to 50%) where it is made the anode for 2 to 5 min at a current density of from 100 to 150 amp per sq ft.

High current densities and low temperatures (50 to 90 F) are favorable for the production of a bright surface. If the current density is too low or the temperature too high, the surface will be clean but not bright; however, higher temperatures can be offset, to some extent, by higher current densities. The production of the bright surface may be caused by the formation of persulfuric acid, which is favored by low temperatures and high current densities. The current density referred to is the initial value; polarization sets in rapidly and the current density drops quickly with a cleaning and then a brightening of the work.

The process imparts a silvery surface free from smut and scale with only a small amount of etching and a considerable reduction in embrittlement from the anodic treatment. Good electrical contacts are needed for maintenance of high current density. Also the acid must be cooled for the anodic treatment.

Coloring Steel

By C. B. F. Young*

STEEL may be colored by heating clean surfaces in contact with various solids, liquids and gases, or by coating the metal with certain solutions and then heating to slightly elevated temperatures. Electrolysis in special solutions will also color steel surfaces without the deposition of a metallic coating.

Coloring of Steel in Molten Salt Baths. Iron and steel that have been polished and cleaned may be colored effectively in molten salt baths; however, the temperatures required are often high enough to decrease the hardness of the metal. Then too, the loss by drag-out may be so great in some types of salt that the metal is too expensive for most purposes.

Both these disadvantages may be avoided by the use of sodium hydroxide baths, since the operating temperatures are moderate (300 to 400 F) and the drag-out is low. Sodium hydroxide baths should be covered so as to exclude all carbon dioxide, which unites with the sodium hydroxide to produce sodium carbonate. If this compound is formed, it can be precipitated by the addition of unslaked lime.

A black color can be produced in a solution of 400 g of sodium hydroxide, 10 g of potassium nitrate and 10 g of sodium nitrate dissolved in 600 ml of water. The solution should be used at 250 to 285 F. The black color appears in 15 to 30 min. Then the object should be rinsed in hot water, dried, and immersed in hot oil.

Color Produced by Temperature. One of the oldest methods of coloring iron and steel consists in heating the material to the desired temperature, and holding it there for a definite period. While steel is being heated gradually through a range of temperatures, each degree of temperature for a given specimen of steel produces a corresponding shade, from straw yellow through brown and purple to dark blue. Each of these colors can be produced by proper control of the temperature.

Below is a table showing at what temperature each of the possible colors is produced. These data are only general; different steels will vary somewhat.

Deg Fahr	Color
400	Faint straw
440	Straw
475	Deep straw
520	Bronze
540	Peacock
590	Full blue
640	Light blue

The colors produced by the above method are ordinarily not uniform, because of the fluctuation of the temperature. If the steel objects are immersed in a molten bath of lead or salt, as described below, the temperature can be controlled much more successfully.

Polished strip steel becomes straw-colored or blue when it has passed through a small lead bath at a suitable temperature and speed. The desired color develops after the steel leaves the bath and comes in contact with the air. The amount of coloring is controlled by passing the strip steel through wet waste located a short distance from where the strip emerges from the lead.

Strip steel is colored satisfactorily also while being passed through a salt bath. The coloring takes place in the bath. Then the adhering salt must be washed off with hot water, and the steel must be dried before it is wound on the reels.

In both methods the strip steel must be thoroughly cleansed and dried before coloring, and must be free from oil and finger marks.

Sand may also be used as the heating medium. The sand may be on a hot plate, or better, in a cylinder that can be rotated slowly and heated by a gas flame underneath. From 5 to 10 min will produce a fine rich blue when the temperature of the sand is approximately 650 F.

The work pieces may also be placed in a sheet metal box with a small amount of sand. The box and contents are agitated back and forth over a fire.

For using either method, experience will be required in order to know exactly when to remove the work material from the fire. The sand is sifted out through a wire sieve and the metal is dipped into oil to set the color.

For tinting steel on a large scale, continuous sand tempering machines are often used. The work material is carried through a perforated drum and heated sand is sifted automatically into the drum. Adjustments of the temperature and rate of feed may be made in such a way that a uniform color is given to a continuous stream of work pieces.

Heat tinting may also be done on a large scale in a rotary retort without the use of sand. The tint is controlled by the operator, who must regulate the temperature accurately and keep close watch of the work material to be certain that it is removed when the desired color is secured.

For continuous simultaneous heat tinting and tempering, machines are procurable with or without sand as part of the process. The sand serves to cushion the work in order to prevent battering that might result from tumbling articles of certain shapes and weights; furthermore, the heated sand ensures complete diffusion of the heat throughout the mass of work and therefore greater uniformity in color.

In all heat tinting, it is important that sufficient time be allowed for oxidation of the steel at the low temperatures used.

Niter Baths. Steel articles that have been polished and properly cleaned, can be given a simple finish by immersion in molten niter. A mixture of half-and-half sodium nitrate and potassium nitrate is melted in a cast-iron or steel melting pot of shape and depth to suit the work. Because rust from any source affects the color of the work, the pot should be cleaned before the saltpeter is put in. The niter is melted, superheated to a temperature of about 900 F, and manganese dioxide is added in the ratio of about 1 part oxide to 50 parts niter, by volume. The manganese gives the molten salt a greenish-black tinge, and causes all suspended matter to settle to the bottom of the pot.

The addition of potassium nitrate increases the cost of the process. Potassium salts are considered necessary when low-temperature operation is desired. Potassium salts may be omitted from the bath, however, with equally good results. Sodium nitrate or Chile saltpeter is an excellent bluing medium, although higher operating temperatures are imperative.

Since bluing by this process forms an iron oxide film on the work pieces, consumption of the manganese dioxide would be expected. One pound of manganese dioxide should be added every 3 hr to a 300-lb batch of saltpeter in order to keep the bath in condition. Although the exact function of the manganese dioxide is still in question, observations indicate that if manganese dioxide is omitted from the pot, the melt does not produce good work. Baths that were found, during analysis, to be charged with iron oxide, gave bad results, whereas no excess iron oxide was found in solution in any bath containing an excess of manganese dioxide. (However, manganese dioxide has been omitted from some baths with satisfactory results.)

In a niter bath a peacock blue or temper blue can be obtained consistently in the following manner: The articles to be blued are first cleaned and polished. The higher the polish, the brighter will be the blue color. A thin coating of oil is then applied and the articles are immersed in the hot niter at 600 to 650 F. The pieces may be suspended individually on wires. Screws, nuts and other small articles may be dipped, enclosed in a wire basket. The parts are held in the niter for a few minutes, after which they are raised to permit observation of the depth of coloring attained. They are then replaced in the molten salt until they acquire the desired color. The time required varies with the temperature and with the size of the pieces, but is never more than 4 or 5 min.

* Electrometallurgist, Leonia, N. J.

The oxidation reaction is the same as is obtained when tempering steel to color. If steel objects are left in the niter too long (for example, 10 min) the film produced will not be a temper blue or a gun-metal blue, but a dirty gray. Preliminary cleaning in gasoline or a similar solvent, produces a bad finish, resulting in a mottled dirty surface. The oil carried on the surface of the parts takes fire as soon as they are immersed in the hot niter and, if any moisture is present on the articles, the hot salt will spatter dangerously.

After the right blue has been obtained, the articles are quenched in clean, cold water; then they are immersed in boiling water and finally in hot oil. A dip in hot oil is necessary in treating small screws or other tiny parts, since it removes all moisture, which, if left on the blued article, may form a spot of red oxide rust at the roots of threads or any re-entrant angle. A darker gun-metal blue may be obtained at temperatures around 1000 F.

Care should be taken not to dip articles, after adding manganese dioxide to a niter bath, until the suspended oxide has sunk; otherwise dirty spots will appear on the blued metal. Cast iron, if highly polished, will take on a gun-metal blue corresponding to that given to polished steel, but cast iron requires about 20 min of immersion at 1000 F to accomplish this result.

Charcoal Bluing. The charcoal bluing process consists in placing highly polished work in a bed of hot charcoal approximately 2 ft deep. The lower layers of the fuel are in a state of incandescence, whereas the upper layers have temperatures suitable for the development of oxide colors. After the desired shade of blue has been developed, the work is rubbed vigorously with waste that has been dipped in raw sperm oil.

Oil Blackening. To blacken in oil, the polished steel part is packed with spent carburizing compound in a carburizing box that is properly luted to exclude air. Box and contents are heated to 1200 F, requiring about 1½ hr. At this temperature the box may be drawn, the lid may be opened, and the parts may be riddled free from carburizing compound and quenched at once in oil. A black oxide skin is formed, dull in appearance but uniform in texture.

A comparatively good black color can be obtained quickly by heating the work to a temperature of 1000 to 1200 F and quenching in oil. The appearance of this finish depends on the surface of the work before heating. This finish is inferior to the gun-metal finish, both in color and in lasting qualities.

Small typewriter parts are given a black finish by heating in a rotary retort furnace to about 750 F. After the work has reached the desired temperature, a small quantity (about 1 oz) of linseed oil or fish oil is added to the charge in the retort. The work is revolved from 3 to 10 min longer; then it is taken from the furnace and spread in pans to cool in the air. After cooling, the parts are dipped into an oil that retards rust.*

For oil blackening and tempering simultaneously, articles that have been quenched in oil from the hardening temperature should be placed, while still covered with the quenching oil, in a rotary drum retort (not perforated). Then they should be heated to a temperature between 600 and 650 F and held at temperature long enough to temper properly and to produce the finish desired. The longer the time, the deeper and more durable the black color. The retort and its contents should be allowed to cool to a temperature lower than 500 F. Then the articles may be discharged and tumbled for a short time in granular cork that is slightly oily, to brighten the black color.

Gun-Metal Finish. The gun-metal finish, also known as "carbonia finish", used on a majority of rifles, shotguns, and revolvers, is used too for finishing small parts, such as buttons, screws, pen points, buckles, pins, saw teeth, links for bicycle chains, and parts for typewriters and calculating machines.

Various types of black finish can be secured, depending principally on the finish of the part before the special treatment is given. Cold drawn or highly polished parts will take a glossy black finish. Parts made from ordinary stampings will have a somewhat duller finish, while work that has been sandblasted, before this treatment, will have a black matte-like finish.

Although unable to prevent rust entirely, this finish acts to retard the formation of rust.

For application of the gun-metal or carbonia finish, the work pieces are placed loosely in a retort with a small amount of charred bone and are heated to a temperature between 700 and 800 F. After the articles have been thoroughly oxidized, they are allowed to cool to about 650 F, when a mixture of bone and 1 or 2 tablespoonfuls of carbonia oil are added. Heating is then continued for several hours. When the work pieces come from the retort, they are a dull grayish black. A uniform black finish is secured by dipping the articles in sperm oil or tumbling them in oily cork.

If the suggested temperatures will temper too much, a temperature as low as 500 F can be used, but this lower temperature requires a longer time at temperature to color the articles and the color is not so lasting as the color produced at the higher temperatures.

Gun-metal or carbonia finish may be applied to articles that have first been nitrided. The result is a pleasing finish that resists rusting and retains surface hardness on the articles, since these coloring temperatures do not soften nitrided articles.

Coslettizing, Parkerizing and Barffing. In Coslettizing, the articles, polished and cleaned, are placed in a solution of ferrous phosphate made from iron filings, about 1% of phosphoric acid, and water, boiled together for approximately 2 hr. On steel this treatment produces a strongly adhesive light gray coating of basic iron phosphate. Because of the low temperature used, the mechanical properties of tempered steel articles are not affected. Even fine springs and magnets are unaffected.

The method called "Parkerizing" differs from Coslett's original method by adding an oxidizing agent and catalyzer, usually manganese oxide (MnO), to the 1 to 2% solution of phosphoric acid that contains ferrous phosphate. The coating produced is then a basic ferrous-ferric phosphate. The ideal coating is one that contains 3 parts of ferrous phosphate to 1 part of ferric phosphate. The articles are gray after being coated. After drying they are usually coated with paraffin oil to give them a deep black color. Considerable variation of color is possible by this treatment. When the articles are first placed in the bath, a large quantity of hydrogen gas is liberated. As soon as the evolution of gas ceases, the process is completed.

Barffing renders the metallic surface rather inert by producing a coating consisting of magnetic oxide of iron. This change, reaching to an appreciable depth, gives the surface the same durability as does a gun-metal finish. The articles to be treated are cleaned and placed in an airtight oven that has a connection introducing superheated steam at 60 to 100 psi. When the articles have been heated to a dull red, the steam is introduced. The coating is resistant to heat. These coatings can be dyed and treated with oil or wax to increase their resistance to moisture. The natural appearance before sealing is a light bluish slate color, which darkens when oil or wax coatings are applied. These coatings prevent finger marking.

Browning. There are many processes for browning steel. However, the procedures may be summarized by describing one process, in spite of numerous variations, chiefly in the composition of the browning mixture. Other variations occur in manipulation and in the atmospheric conditions, artificial or natural. The longer browning processes have relatively low temperatures and humidities; the shorter processes have relatively high temperatures and humidities. Conditions for rusting are poor in the longer processes and good in the shorter ones.

Procedures in Browning. The articles are first cleaned thoroughly. One way to accomplish this is to boil them for 15 min in a soda solution. Any grease appearing on the surface of such a solution indicates the need for adding soda ash. Then the parts should be dried on a draining rack. When they have cooled to approximately 120 F, they should next be coated with the browning solution, which should be applied evenly over the surface with a brush or sponge, or as a dip. The articles should be permitted to dry for about 30 min before application of a

second coat of the solution; thereafter they should dry again for 30 min.

The work pieces are then placed in a warming room or cabinet, and brought to temperature, which may vary from 140 F to as high as 175 F. Dry heat is satisfactory, since its function is merely to heat the articles to such a temperature that when they are placed in the humidor rusting cabinet, dew will not form on the surface, causing spots in the color.

The time in the warming room will naturally vary according to the size of the pieces. From the warming room they should be transferred to the rusting room, which must be at the same temperature as that of the warming room (175 F). Humidity as high as the saturation point is desired, but danger of condensation should be avoided, because pitted and spotted work will result if the dew point is reached. Articles are rusted in approximately 1½ hr for such shapes as bayonets; others take shorter or longer periods, depending on the size and surface.

The rusted metal, now a dirty greenish red, is removed from the humid room to a third cabinet or room, where the conditions are the same as in the first room. This transfer is not absolutely necessary, but the purpose is to set the rust. The rusted metal is allowed to remain in this room for 30 min before being placed in clean, boiling water for 15 min. After this time, the articles are allowed to drain dry, and then are carded on a wire brush or fiber wheel, which removes any loose particles of oxide from the surface, thus completing the first coating.

Three more rustings are applied in much the same manner, after which the browned surfaces are given a coating of thin white slushing oil.

All the rooms should have proper thermometer and thermostatic controls, and the rusting room requires a recording hygrometer. Temperature and moisture should be controlled automatically. The layout of the apparatus should permit a proper flow of work between processes.

For compositions of browning solutions, see Table I.

Electrolytic Coloring. When iron or steel is covered with an electrolytic coat of another metal or alloy, the result is not considered coloring but protecting the base metal. Thus, iron and steel are colored yellow by a deposit of brass; red by a deposit of copper; black by a deposit of black nickel; and white by a deposit of a nickel-cobalt alloy. See pages 718 and 719 for typical compositions of baths and conditions for electrodeposition of metals.

Aside from the deposition of metals and alloys, the deposition of colors by the aid of an electric current is producing good results. Examples are as follows:

Blue on Iron. A good blue can be produced on iron by first depositing on the surface a thin coating of electrolytic copper, using either the sulfate or cyanide bath. The copper-coated steel is then made the cathode in a solution containing 1.25 oz of cupric acetate per gallon and 0.50 oz of gelatin per gallon. A current of 1.5 to 4.0 amp per sq ft should be passed through this solution, using copper as the anode. After depositing the copper from this solution for about 15 to 20 min, the cathode should be washed in water and immersed for 5 min in a 5% cupric acetate solution. Hues of startling intensity are produced one after another, until finally a deep blue develops.

Color Plating. The colors produced by this process have a metallic luster, are free from dyes or pigments and are light-fast. Almost all the colors of the spectrum from violet to red can be produced in a single bath. The colors obtained depend on the thickness of the deposit and this in turn depends on the plating time, which may vary from 1 min to 30 min or more.

The bath is composed of complex organic compounds. The work metal is made cathode while copper is used as the anode. The current density is approximately 0.5 amp per sq ft with about 0.4 volt.

The finish of the base metal determines the appearance after color plating. Thus an article that is highly polished before color plating has a similar polished appearance after color plating. A clear lacquer is applied, after color plating, to increase the resistance of the finish to wear and corrosion.

Molybdate Method. If iron or steel is made the cathode in a bath containing 7 to 14 oz of ammonium molybdate per gallon, with enough ammonium hydroxide to produce a clear solution, and 1 to 10 amp per sq ft is passed through the cell, various colors and hues can be obtained. The colors change several times in a cycle. When a cycle is complete, the colors are reproduced in a somewhat darker shade. If this procedure is allowed to continue, black deposits are finally produced, although most of these deposits have the disadvantage of being brittle. Such a bath, with modifications, can be used for coloring various metals, including aluminum.

Phosphate Coating

By V. M. Darsey*

PHOSPHATING is the chemical treatment of iron, steel, zinc, cadmium, aluminum, and their alloys, by means of a dilute acid phosphate solution saturated with one or more of these metals, so that the metal surface is converted to an insoluble crystalline phosphate coating. The protective coating, integral with the surface of the metal, results from chemical reaction between phosphoric acid and the metal, as contrasted with metallic or paint coatings, which generally do not require chemical combination with the base metal. Reaction of the acid with the metal takes place with the evolution of hydrogen, until the entire metal surface is converted to a uniform phosphate coating. To accelerate the formation of the coating, an oxidizing agent is used,[1] capable of oxidizing hydrogen and thus preventing the formation of a hydrogen film on the metal

* President, Parker Rust Proof Company, Detroit

surface during treatment. The characteristics of the coating, such as thickness, crystalline structure, and the extent of the penetration of the coating into the base metal, can be controlled by the following factors: the method of cleaning before treatment, the method of applying the solution, duration of treatment, and modification of the composition of the solution.

The advantage of these factors has been utilized in processes for producing phosphate coatings that are especially suitable for preventing corrosion, and that serve as a base for paint, resist wear, and facilitate the deep drawing of metals.

The method of applying phosphate coatings is usually determined by the size and shape of the article to be coated. Small items, such as nuts, bolts, screws and small stampings, are coated in tumbling barrels by immersion in the phosphating solution; whereas, large fabricated articles, such as automobile bodies and refrigerator cabinets, which are difficult to immerse, are coated by spraying the solution on while they are on conveyers. When steel sheet and strip are to be coated, the metal is usually passed continuously through the phosphating solution or the solution is sprayed onto the steel while rubber rolls or brushes expedite the formation of the coating.[9]

Corrosion-Resisting Phosphate Coating. Phosphate coatings were first used to protect iron and steel from corrosion. The conversion of a metal surface to an insoluble phosphate coating, acts as a physical barrier to exclude moisture from the metal surface. The protective value of such coatings thus depends on continuity and, for this reason, thickness and density of coating are more important than any other factors. Coatings can be produced with a wide range of thickness, depending on the method of cleaning before treatment, adjustment in the concentration of the solution, and duration of treatment. A build-up of 0.00015 to 0.0003 in. of phosphate coating ordinarily results when articles are Parkerized. No electric current is used and formation of the coating depends entirely on contact between the phosphating solution and the metal surface. Because of this fact, uniform coatings can be produced on irregularly shaped articles, in recessed areas and on threaded as well as on flat surfaces.

The affinity of heavy phosphate coatings for oil, wax or color is one of the most valuable characteristics utilized in practice to increase the corrosion resistance of these coatings. Frequently phosphate-coated articles are finished by a dip in nondrying or drying oils that contain corrosion inhibitors, and are then drained or centrifuged to remove the excess.

A recent development is the production of phosphate coatings in color, with more than twice as great resistance to corrosion as coatings without the color treatment. The phosphate-coated articles are immersed in the color bath at boiling temperature for 2 to 6 min, and are then rinsed thoroughly in water. The color results from chemical reaction and is insoluble in water. Because of fading somewhat, as a result of exposure to sunlight, certain colors are not recommended for outdoor use where rigid color fastness is required.

Phosphate Coating as a Base for Paint. In general, the useful life of any paint finish depends on two major factors—the durability of the organic coating itself, and the adherence of the film to the surface on which it is applied. Permanent adhesion is clearly the primary requisite for improving practice in painting most metals. Surface treatment[2, 3] is emphasized in preparing metals for painting; and in most instances, the treatments recommended have as their main objective the formation of a stable and nonreactive coating, combined with the base metal, so as to retard corrosion and also to provide greater adhesion of applied paint films. The primary function of any protective coating of paint is to prevent corrosion of the base metal in the environment in which it is used. To accomplish this purpose best, the method of preparing the metal should reduce the activity of the metal surface, so that underfilm corrosion is prevented at the interface between paint and metal. Wherever the paint film is scratched or abraded the spread of rust is reduced on phosphate-coated steel.

It is common practice to apply various types of air-drying paint and of paint that requires baking, over phosphate-coated steel. Enamel that is baked at a temperature as high as 400 F can be applied successfully to phosphate-coated steel.

Difference Between Metals Cleaned in Phosphoric Acid and Those Coated With Phosphate. Phosphoric acid metal cleaners usually consist of phosphoric acid and a water-soluble, organic grease solvent, with or without a wetting agent. In the preparation of metal with such solutions the purpose[4] is to remove grease and rust in one operation, and to provide a slight etch of the metal to promote the adhesion of paint. For accomplishing this result, the cleaning solution must contain sufficient acid and solvent to remove rust and grease. Of necessity, this concentration is such (15 to 20% H_3PO_4) that the formation of any substantial phosphate coating is prevented. When metal surfaces are to be given a phosphate coating, the articles are first freed of rust and grease by suitable cleaning methods, and are then treated with a balanced dilute acid phosphate solution (0.6 to 1.0% H_3PO_4), so that reaction of the acid with the metal results in the conversion of the surface to a crystalline phosphate coating. Tests made on steel cleaned with phosphoric acid have revealed that the phosphate film remaining from the cleaning operation, averages only 5 to 10 mg per sq ft of surface. In the preparation of steel for painting, treatment with a phosphate coating (Bonderizing) produces from 100 to 400 mg of coating per sq ft of surface, depending on the method of appyling the solution.

Phosphate-Coated Steel for Containers. It is generally recognized that paint coatings applied to phosphate-coated articles are more serviceable than those applied to untreated articles. In 1940 a method[5] was developed for producing on sheet and strip steel at the mill, a phosphate coating that, in addition to inhibiting corrosion and increasing the adhesion of applied paint coatings, will withstand drawing, bending and other mechanical deformations required in the manufacture of caps, crowns and cans. This development has saved tons of tin and has become a recognized method of preparing steel for painting in the container industry. The availability of such phosphate-coated steel, permits painting flat sheet or strip and forming articles from it with the advantage of good paint adhesion and resistance to corrosion.

Phosphated Zinc-Coated Sheet and Strip Steel. Zinc has long been used to protect steel against corrosion. However, it is now used in conjunction with a phosphate coating, to produce sheet and strip steel with superior resistance to corrosion and greater ability to retain paint. The finish consists in the electrodeposition on steel of a uniform coat of zinc, having a minimum thickness of 0.000020 in., and then the phosphate treatment. The deposition of zinc and the phosphate coating is accomplished by passing the steel through a zinc-plating bath, rinsing, and then immediately phosphating. The outer surface of the zinc is converted to an insoluble phosphate coating, but a layer of metallic zinc remains between it and the steel for added resistance to corrosion. This finish makes available corrosion-resisting steel, especially suitable for the fabrication of articles where assurance is needed that the coating will provide an excellent base for applied paint finishes. Success in shipment and storage with freedom from rusting make this steel especially suitable for many uses; thus manufacturers may have the advantages of plating and phosphating without the expense of installing such equipment. Comparison of paint finishes applied over untreated and over phosphate-coated zinc, shows the advantage of surface conversion of the zinc before painting.

Wear-Resisting Phosphate Coating. Various materials and methods are employed to reduce wear on bearing surfaces. There is common agreement that it is essential to maintain an oil film between moving parts, thus preventing metal-to-metal contact, if serious wear is to be avoided. Experience has established phosphating as a widely used method[6] of reducing wear on machine elements. Treatment of properly cleaned iron and steel parts by immersion in the hot phosphating solution for 10 to 15 min, results in the conversion of the metal surface to a nonmetallic oil-absorptive coating, consisting chiefly of

iron and manganese phosphates. The uniformity of the phosphate coating, the penetration of the coating into the metal and the affinity of the coating for oil are considered the most valuable properties in reducing wear. The phosphate coating permits new parts to be broken in rapidly by providing adequate oil on surfaces at such critical times.

A wide variety of parts are phosphate-coated to retard wear, including cylinder liners, pistons, rings, camshafts, valve tappets, gears and many other parts used in machine assemblies.

Phosphate Coating as an Aid in Drawing Steel. The commercial practice of providing a phosphate coating on steel to facilitate drawing,[7] has been common in Europe for several years, and the use of this method is rapidly increasing here.[8] The power employed in deep-drawing operations sets up a great amount of friction between the steel surface and the die. The phosphate coating of steel before drawing, reduces this friction, increases the speed of the drawing operations, reduces the consumption of power and increases the life of tools and dies. When phosphate-coated steel is used in drawing seamless steel tubing, the resulting decrease in friction is so pronounced that greater reduction of tube size per pass is possible. Sometimes the reduction is as great as one third.

Reduction in the number of draws and anneals, in the deep forming of articles, results in economy of operation. Conversion of the steel surface to a nonmetallic phosphate coating permits the distribution and retention of a uniform film of lubricant over the entire surface of the steel. This combination of lubricant and nonmetallic coating prevents welding and scratching of steel in the drawing operations, and greatly decreases rejections.

Rust-Preventive Compounds

By Howard B. Carpenter*

BEFORE World War II, rust was accepted by many as a necessary evil, partly because of the poor performance of many of the available rust-preventive compounds. Then during the years of war production, many manufacturers were faced for the first time with the necessity of protecting metallic products and equipment against the effects of wide extremes of temperature and humidity, as well as against the corrosive action of sea water. Old methods of packaging were inadequate without an actual rust-preventive film on the surface of the metal itself. In addition, increased precision, involving better finishes and lower tolerances, has necessitated protection for parts in process, and greater decentralization in manufacture has required that assembled units be prevented from rusting during shipment and storage.

For many years, paint and resistant metals, such as tin, lead and zinc, were the principal rust preventives, but the difficulty of removal made such coatings impracticable for finished surfaces, especially for surfaces subject to sliding contact, where rust produces heavy financial losses. Until a few years ago the protection given to such surfaces usually consisted of a so-called "slushing compound" of petrolatum and oil. The protection, however, was not reliable, since uninhibited oil, petrolatum or grease cannot be depended on to prevent rust. As a result of the combined efforts of the Armed Forces, the manufacturers of metals, instruments and machinery, and the compounders of rust preventives, highly effective products have been developed scientifically and their value has been demonstrated under extremely severe conditions. At the same time, industry has come to realize that the use of these inexpensive compounds will minimize one of the greatest sources of economic waste.

The principal function of rust-preventive compounds is to act as a barrier to moisture. Some of them also afford protection against the action of corrosive gases, but this is usually a physical and not a chemical action.

Rust-preventive compounds are *not* rust removers. Furthermore, they are effective only when applied to surfaces that are *thoroughly* clean and dry. This should be emphasized strongly, since the best rust preventives are virtually worthless if applied to a dirty or moist surface. Rust itself is spongy and, if not removed, is likely to retain moisture, thereby promoting corrosion under the film.

Modern rust-preventive compounds are described below, but the comments should be considered of a general nature, since undoubtedly there are exceptions. These compounds are of two general types, which in turn may be subdivided.

Non-Hard-Drying Types. This is the predominant classification, which includes coatings that do not dry to a hard film. In general, these products have a petroleum base and are characterized by ease of removal with petroleum solvents, without adverse effect on the metal surface to which they have been applied. Because of the petroleum content, many of these products will serve as lubricants, if for any reason they are not removed before operation. This group of compounds can be subdivided as follows:

Plastic Type. These are greaselike materials. The heaviest grade usually consists of petrolatum plus rust inhibitors. Other grades, softer and with somewhat lower melting point, are obtained by adding an oil of fairly high viscosity to the petrolatum base. As the consistency of products of this type decreases, the ease of applying and removing them increases, as well as the coverage per gallon; however, the anticipated protection decreases.

These plastic compounds are characterized by moderate resistance to abrasion, a fair amount of self-healing power if film rupture occurs, and the ability to expand and contract with the metal. They also resist displacement that results from contact, under pressure, with the interior surface of a shipping container. Under conditions that involve direct exposure to the elements, the heaviest grade affords the best protection of any in the removable category. Its outer surface hardens slowly when exposed to the atmosphere, but the film underneath retains its original softness and self-healing properties. The plastic type should be used wherever possible, except where the solvent type of products will give adequate protection, as in certain phases of indoor storage.

Fluid Type. These materials consist of petroleum oils of various viscosities, to which rust inhibitors have been added. As a general rule the fluid type of compound is used where the application of the plastic type would be difficult or unsuitable—for example, in oil-lubricated bearings, hydraulic systems, turbines, gear cases and such. However, the fluid type may drain or be removed by wick action, thus giving less permanent protection than that afforded by the plastic type.

Internal-Combustion Engine Type. This modification of the fluid type includes a neutralizer for the acidic products of combustion, plus other additives that make the compound suitable for use as a motor oil, thus ensuring against damage if replacement of oil is neglected when the engine is recommissioned.

Thin-Film Type. Products of this type contain a high

* Engineering Division, Standard Oil Company of New Jersey, New York

percentage of a petroleum solvent, which evaporates, leaving a reasonably hard, thin nontransparent film. These materials are usually considered suitable for either outdoor or indoor service, as alternates to the plastic type.

Solvent Type. In general, these products consist of solutions of rust inhibitors in mineral spirits that evaporate, leaving a thin, transparent, but effective rust-preventive film. This film does not dry hard but remains somewhat flexible and tacky over long periods. These solvent products are not suitable for use outdoors, but give excellent indoor protection, particularly on material or parts in process, without interfering with visual inspection or the reading of identifying marks. One special modification of the solvent type of rust-preventive compound is made of materials that give it special protective ability. When this substance is applied to a wet surface, the water is immediately and completely displaced, fingerprint residues are neutralized, and the surface is left coated with an effective rust-preventive film.

Hard-Drying Types. The other general category is the hard-drying group. These compounds, usually of the so-called "lacquer" type, provide a film that is hard yet sufficiently flexible to resist abrasion in shipping and to resist cracking from the expansion and contraction of the metal. The hard-drying types are transparent, hence do not hide defects or the markings meant for identification. The protective film can be machined off, left to wear off, or painted over with pigmented products. The conventional compounds of this class dry to touch in 4 to 6 hr and dry hard in 24 hr. Grades that dry more rapidly are also available.

One special material in the hard-drying group is an aluminum paint with a special vehicle that is highly resistant to the particularly severe action of hot oil, hot water, or a combination of the two. This coating is satisfactory for the protection of the interiors of lubrication systems and sumps, hydraulic gear cases and other surfaces that are subject to the same type of corrosive action.

Another type of inhibited oil should be mentioned to prevent further acceptance of a misunderstanding. Many prime-grade turbine oils contain what is called a "rust inhibitor". This is not a misnomer but refers only to protection from rust resulting from the presence of water with which a lubricant has become contaminated. Such inhibitors are not expected to furnish protection against humid or corrosive atmospheres.

Methods of Test. The development of effective rust preventives has necessitated the development of laboratory methods for the evaluation of performance. Considerable progress has been made, but further improvement is desirable, and a means is needed for predicting service life from laboratory results. The most commonly used test of performance is carried on in a "humidity cabinet", where mild steel panels (usually 2 by 3 in. or 2 by 4 in. and $\frac{1}{16}$ or $\frac{1}{8}$ in. thick) that have been sandblasted or polished, are coated with the material under test and exposed to a temperature of 100 or 120 F and a relative humidity closely approaching 100%. The rust preventives are rated by the number of hours that elapse before rusting occurs. This test indicates the relative protection to be expected from exposure to atmospheric humidity.

In the salt spray test, similar panels are exposed to an atmosphere of atomized sodium chloride solution. The results give a fair indication of the relative protection to be expected from exposure to salt-laden atmospheres, such as those encountered in ocean shipment. Another test, involving immersion in synthetic sea water, gives similar indications.

A water spray test and exposure in a weatherometer indicate relative resistance of rust-preventive compounds to removal by the action of the elements, as well as resistance to the corrosive action of the elements.

The results from these tests are less reproducible than might be desired, but they are informative provided it is realized that they indicate simply an order of magnitude. For example, a product that furnished protection for 225 hr in a humidity cabinet, should not be classed as superior to one that served for 200 hr. A product that protected for 200 hr should be considered better than one that gave 100 hr of protection, but there is no reason to assume that the protection would be twice as long in actual service.

The hard-drying types of rust preventives are usually tested by exposure of panels to the weather, at an angle of 45 deg, facing south, in the same manner as panels are arranged for the testing of pigmented coatings.

Surface Preparation. Rust preventives should be applied only to surfaces that are thoroughly clean and dry, with the single exception of the application to wet surfaces of a solvent type of product with water-displacing properties.

No one general method of cleaning will condition all surfaces suitably for the application of protective coatings. Rust that has already developed may be removed successfully by the use of steel wool, a wire brush, or even sand blasting or shot blasting. A hot alkaline bath followed by thorough rinsing is also suitable. Chlorinated solvents are satisfactory cleansers, although care must be taken to ensure that no chlorine is liberated in a way that will permit a union with water, thus forming corrosive hydrochloric acid. Where the contamination consists of dirt held in place by oil or grease, the use of petroleum solvents is probably the most efficient cleaning method. Mineral spirits, also called "Stoddard Solvent" or "dry cleaners' fluid", is the most generally used petroleum product, having the advantage of a rate of evaporation higher than that of kerosene without increasing the fire hazard, according to the classification of the Underwriters' Laboratories, Inc. The use of kerosene should be avoided because it promotes corrosion. Care should be taken to keep a petroleum solvent from contact with rubber or other materials that would be affected. The use of a clean solvent is essential.

Fingerprints promote active corrosion. Gloves of canvas or synthetic rubber provide the best protection. However, to wear gloves is not always practicable and, although bare hands do not necessarily deposit fingerprints, the chances are great enough to warrant preventive measures. These deposits are not removed by mineral spirits or other cleaning agents that are used commercially. Conventional rust preventives are also ineffective, but the solvent products, to which agents have been added that neutralize fingerprints, have proved very effective over a considerable period of time. The efficacy of some of these special solvent-type products is improved by the addition of 5 to 10% water. Special products of the solvent type that are able to displace water and to neutralize fingerprints, besides preventing rust, have found wide acceptance in industry.

The removal of moisture or a soluble oil emulsion from a surface before the application of a rust preventive, is often less simple than it appears. Compressed air that has been well filtered and dried is suitable for removal of moisture, but the air from regular shop lines is not suitable. Cloths are sometimes used but it is difficult to keep them clean and dry, and objectionable lint may be left on the dried surface. Ovens are also used, but none of these methods is suitable for the removal of emulsions; furthermore, such methods leave the part unprotected during the period between drying and coating with the final rust preventive. Here again a solvent type of rust preventive with water-displacing qualities has evident advantages.

Methods of Application. Although the supplier of a rust-preventive compound is best qualified to specify the detailed procedure for application, the following general comments may be helpful. After the metal article has been cleaned, a suitable rust-preventive compound should be applied as promptly as possible and in such a manner as to provide a uniform and continuous coating to the surfaces to be protected. Dipping is preferred wherever possible, because it ensures complete coverage; however, spraying is effective, as well as application by brush, swab or roller.

In the application of compounds of the plastic type, the piece being dipped should be immersed long enough to increase the surface temperature nearly to the melting point of the compound. Otherwise a poor bond may be expected. For the same reason care should be taken to prevent too rapid chilling when any compound of the plastic type is applied by brush or swab. In general the plastic type of compounds cannot be sprayed, although equipment is available for applying the softer grades by this method.

As an alternate to heating, the plastic type of products may be cut back with mineral spirits that evaporate after application. Heating is preferred, however, since it affords somewhat better protection and does not require time for the evaporation of the solvent.

Whenever possible, rust preventives of the fluid type should be drained, filtered and reused, with the exception of the internal-combustion engine type, in which—to some extent at least—the acid-neutralizer is consumed in service. Therefore, reuse of compounds for preventing rust must be confined to applications that do not require the neutralizing of acids. The manufacturer of the rust-preventive compound is the authority best qualified to recommend suitable types of mediums for filtering. In many products, however, the rust inhibitors are in true solution and will pass unchanged through most of the chemically inert filtering mediums. When liquid rust preventives are drained, the film remaining on the coated surfaces will provide full protection, although it is often wise to attach a prominent tag calling attention to the need for refilling with the normal lubricant before operation.

It is often unnecessary to disassemble machinery such as turbines, gear cases and cylinders, for the application of a rust-preventive oil to the interior surfaces. Fogging by high-pressure spray through openings can be effective, although this method must be used with discretion if complete coverage is to be obtained.

The first step in the preservation of internal-combustion engines is to allow them to cool to ambient temperature. The crankcase is then drained, flushed, and refilled with the minimum quantity of rust-preventive oil necessary for safe operation of the engine. After this, the engine is operated for a short period at idling speed and with no load. The rust preventive is then injected into the cylinders above the pistons by slowly pouring it into the carburetor air-intake of spark-injection engines. In diesel engines the rust preventive is used as fuel during the last few minutes of the run. After the engine has stopped and cooled, the spark plugs or fuel injectors should be removed and the preservative should be fogged into each cylinder, with the pistons down in all instances if possible. Before the plugs or injectors are replaced, the engine should be turned over for a few revolutions to obtain complete distribution.

The thin-film type and the solvent type of products may be applied by dipping, spraying or brushing.

Precautions. Care must be taken—especially in the use of petroleum-base rust preventives—not to apply these compounds to nonmetallic parts made of rubber, cork, paper, leather, fabric or plastics. Where contact cannot be avoided by shielding or other means, the heaviest of the plastic type of compounds should be used. This very viscous type will have the least detrimental effect, and probably almost none, since it contains only a little oil.

Special precaution is imperative when rust-preventive compounds are applied by spray. All petroleum products, when atomized, endanger health if they are taken into the lungs in any appreciable quantity. Therefore it is recommended that adequate local ventilation be provided when a petroleum-base product is applied by spray. Proper precautions, as established by the National Board of Fire Underwriters, must also be observed in connection with any possible fire hazard.

Methods of Removal. The rust-preventive compounds that are not hard drying may be removed with petroleum solvents. Mineral spirits is preferred, although kerosene and white gasoline are also suitable. Rags or waste may be used when soaked in hot water, but this method is likely to be more laborious. Many of the rust-preventive compounds are lubricants and need not be removed from bearings, gears and such, although all sumps, reservoirs and crankcases should be drained and refilled with the lubricant recommended for regular service.

Ordinarily no attempt is made to remove the hard-drying compounds, but should this become necessary, the use of a standard grade of paint-remover is recommended.

Typical Applications. Rust-preventive compounds may be used to great advantage on three classes of articles in the metal and metalworking industries.

The first class is machinery or equipment kept in stand-by storage without disassembly. Any attempt to prescribe in detail for this classification would be impracticable, but the suitable types of products and methods of application can probably be determined from the general descriptions given above.

The second group of applications includes (*a*) tools such as saws, drills, cutter heads, dies, molds and gages; (*b*) spare parts such as mill rolls, mandrels, gears, armatures, antifriction bearings, heavy machine parts and housing screws; and (*c*) finished parts, devices or machinery in temporary storage. For tools, rust preventives of the solvent type are usually preferred—particularly compounds that are able to displace water and neutralize fingerprints. To a limited extent the same recommendation applies to spare parts, although in general the plastic compounds are preferred for this class of service. Finished parts, in storage between fabrication and assembly, or finished devices between assembly and installation, should be protected by a solvent type of product, provided the storage conditions are not too severe. Otherwise a plastic type of product is recommended—or a compound of the fluid type, if circumstances prevent the proper application of the plastic compound.

The third category of applications for rust prevention covers finished products. For sheets, strip metal, bar stock and the like, protected from the weather, a solvent type of product should be used. Preservatives of this class have also given very satisfactory service on continuous strip mills and on steel wire between drawing and stranding in the manufacture of rope. For products that are exposed to the elements during shipping, the use of hard-drying rust-preventive compounds should be seriously considered. This type of material has been used on pipe to a considerable extent and it could probably be used profitably on shapes, plates, bar stock and rod in order to preserve mill finish during shipment and storage, which often involves exposure to the weather for long periods. Such coatings are durable, transparent, reasonably elastic, resistant to water and wear, and ordinarily less expensive than paint. Rough handling and expansion and contraction of the metal have little effect. There are a few exceptions to this recommendation; for example, on bar stock fed to automatic machines, this type of coating might interfere with chucking. In such instances, a plastic product of the heaviest grade would provide adequate protection, although removal with a petroleum solvent would be necessary before machining.

For products such as steel rod for wire drawing, it is entirely possible that pickling could be eliminated, and consequently both labor and materials could be saved if a hard-drying coating were applied at the mill.

Other examples might be cited, but as a rule the selection of a suitable type of compound, represents a compromise between ease of application, the severity of the storage conditions and ease of removal. Naturally cost is also to be considered, but the difference in cost among various grades is small enough to place this factor in a position of secondary importance. The cost of improper protection is too great. Ease of application or removal deserves consideration but should not be permitted to have too great an influence, because usually the products most difficult to apply or remove furnish the best protection.

Emphasis should be placed on the definite economic advantage to be derived from the use of good rust-preventive compounds. Removal of rust is expensive. Where remachining is required, a change in dimension results, often necessitating even more expensive machine work on the companion member. Rusty spare parts have caused the loss of valuable machine hours and have even held up plant operation.

Contributors and Principal Changes

AS IN PREVIOUS EDITIONS OF THE METALS HANDBOOK, the Nonferrous Section has been prepared under the direction of the Nonferrous Data Sheet Committee of the Institute of Metals Division, American Institute of Mining and Metallurgical Engineers, through a co-operative arrangement with the American Society for Metals.

After the general plans for this edition were complete, the committee appointed eight chairmen to organize the sections concerning the principal nonferrous metals. In collaboration with these chairmen, many specialists in the nonferrous metals industries have written the articles and compiled the data sheets. Throughout the Nonferrous Section, 217 authors and committee members are named as contributors. Many other metallurgists and engineers have aided directly but anonymously. For instance, more than one-third of the data sheets about specific alloys are credited to the laboratories where the information was assembled, rather than to the numerous individuals who joined in each compilation.

In preparing this edition, the committees and the authors have made two principal changes in the scope and form of the subject matter.

For the first time, discussions of melting, shaping and treating are a prominent part of the Nonferrous Section. Such articles have been given three times as much space as before, and five times as many authors have contributed.

Nearly all the specific data for nonferrous metals and alloys have been presented according to a new, semitabular arrangement. This data sheet form has been used so that the reader can easily find information of the same kind for various alloys by following key numbers, which are the same throughout the Nonferrous Section. This method of presenting the data has also the advantage of being more concise than running text; data for 220 nonferrous alloys are presented on 142 pages.

A few classes of material are described in groups rather than as individual alloys — for example, electrical-contact materials, low-melting alloys, type metals, and silver brazing alloys. Bearing materials are discussed in an article and also, more briefly, in data sheets in the sections that deal with properties of aluminum, copper, lead, and tin alloys.

It has been impossible to include data for all the nonferrous alloys used in industry. In the judgment of the committees, the alloys discussed are the most widely used, or are representative of the important classes of material.

A guide to the use of the data sheets and a list of the key numbers are printed on the inside of the back cover.

Hot Plastic Working of Nonferrous Metals

BY C. H. MATHEWSON*

HOT WORKING is usually defined as working above the recrystallization temperature, so as to ensure recrystallization and recovery or retention of normal properties in spite of the plastic deformation.

A satisfactory scientific foundation for hot working operations would require complete information concerning: (1) stress-strain curves at temperatures throughout the potential hot working range, and with a rate of application of stress comparable with that desired in the intended hot working operation; (2) from such curves, an evaluation of the energy requirements for economical operation, and of the toughness or ability of the metal to withstand the process (thus, the temperature selected for hot working should be one at which there will be no great increase in the yield strength of the metal during working; that is, the metal should have a flat stress-strain curve and there should be adequate elongation before fracture); (3) the effect of prior structural condition of the alloy and in particular of natural impurities; (4) the requirement of special properties in the metal imposed by the special mechanical characteristics of any given process, such as drawing, extrusion, forging, rolling, swaging. Thus, in drawing, the metal must have strength to support plastic alteration while being pulled through the die; however, in swaging, the metal is supported during deformation and may be worked at its minimum plasticity and strength.

The literature of metal technology contains no systematic or satisfactory accumulation of data on these points, or development of other criteria for judging the hot working quality of metal. The performance of a metal in such operations is usually estimated in an approximate, provisional manner by reference to the softening temperature of the metal after cold work, with an increment allowed for the higher temperature necessary to permit virtually instantaneous softening in a rapid deformational process. Data concerning ordinary static tensile strength and ductility at elevated temperatures are now available[1-7] for many of the ordinary commercial alloys, and are of certain value in indicating proper working temperatures. The details of performance are then settled by trial and error. Similarly, the effect of impurities and the requirements of special processes must be established by a suitable empirical testing procedure. Generally, a high value of reduction of area in the tension test at high temperature, accompanied by moderate tensile strength, is considered to be especially indicative of useful plasticity. For example, in the tests reported by Price,[5] the percentage reduction of area of copper exceeds 90 in the temperature range from 930 to 1830 F, with tensile strength decreasing gradually from about 9000 to about 1200 psi. In Table I, 1550 F is given as the optimum hot rolling temperature for copper to maintain softness, but the metal may be hot rolled satisfactorily at all temperatures between 930 and 1830 F, though with some difficulty at the highest temperatures because of the extremely low strength of copper in this region.

Rather definite statements may be made concerning the adaptability of alloys to the various hot working operations. Much information of this character can be found in the articles on metal technology in this Handbook.

For rapid deformations, as in stamping or forging, useful information may be derived from a drop hammer test in which the decrease in height of a cylindrical sample is plotted against the energy of the blow. Commonly, various approximations are accepted, such as compression for a given blow plotted against temperature, or composition,[8, 9, 10] from which suitable temperatures or compositions may be selected when attention is also directed to the manner in which the specimen stood the plastic alteration; for example, whether cracking occurred at the edges.

When the constitution of an alloy changes with temperature, impact tests on notched bars may show with particular clarity the existence of favorable and unfavorable ranges of toughness. Thus the width of the brittle range in brass in the vicinity of 900 F and the effects of zinc, lead and tin are brought into prominence by the Izod test.[11, 12] There are good indications of this weakness in the ordinary tension test for elongation or reduction of area.[4] However, there is probably no test revealing hot shortness, or far-reaching plasticity and toughness, that can be used as more than a general guide for directing experimentation with the particular equipment in which the given alloy must be deformed.

The empiricism necessary in this work is well stated by Morris.[10] "For instance we wish to extrude a metal *M*. We know that we can extrude another metal *Q* at temperature *T*. We make a drop hammer test of metals *M* and *Q* and find that in order to obtain the same reduction in height as we find in metal *Q* at temperature *T*, we must heat metal *M* to temperature *T'*. *T'* is therefore the temperature at which we first try to extrude the metal *M*, with fair assurance that we shall be able at least to force the metal through the die. Much the same kind of reasoning can be applied to hot rolling. The tendency to crack in extrusion and rolling, however, must be ascertained largely through experience."

Concerning the effect of impurities, embrittlement resulting from segregation of a weak constituent in grain boundaries (for example, lead in alpha brass) and the

* Professor of Metallurgy, Yale University, New Haven, Conn.

great increase in resistance to deformation generally produced by solid solution even of small amounts of alloying elements (principally responsible for the contrast in properties between commercial and extremely pure metals) have been studied more in relation to cold working than to hot working but have brought certain well recognized limitations into commercial practice. For example, several hundredths of a per cent of lead prevents the commercial hot working of alpha brass, but with Muntz metal (probably because of more favorable distribution attending the structural adjustment of alpha and beta with temperature in the hot working range)[9] lead in considerable quantity does not prevent the majority of hot working processes. Similarly, tin bronzes that contain the $\alpha + \delta$ eutectoid, show marked brittleness in the Izod test and cannot be hot worked successfully, while bronzes that contain tin in solid solution can be hot worked satisfactorily.[11]

Annealing or recrystallization temperatures, as ordinarily determined, do not properly define the softening points of metal while in a process of rapid deformation. The effect of temperature and rate of loading on hardening is particularly marked in this region of temperature, as may be seen from Fig. 1. The solid curves indicate strengthening in single crystals of cadmium under a load applied at the rate of 140 psi per min, and the dotted curves indicate strengthening under a load applied at a rate 100 times greater. Thus it appears that in a region of low temperature where there is virtually no spontaneous recovery towards initial properties, and in a region of high temperature where the recovery is substantially complete during the test, changing the temperature or the

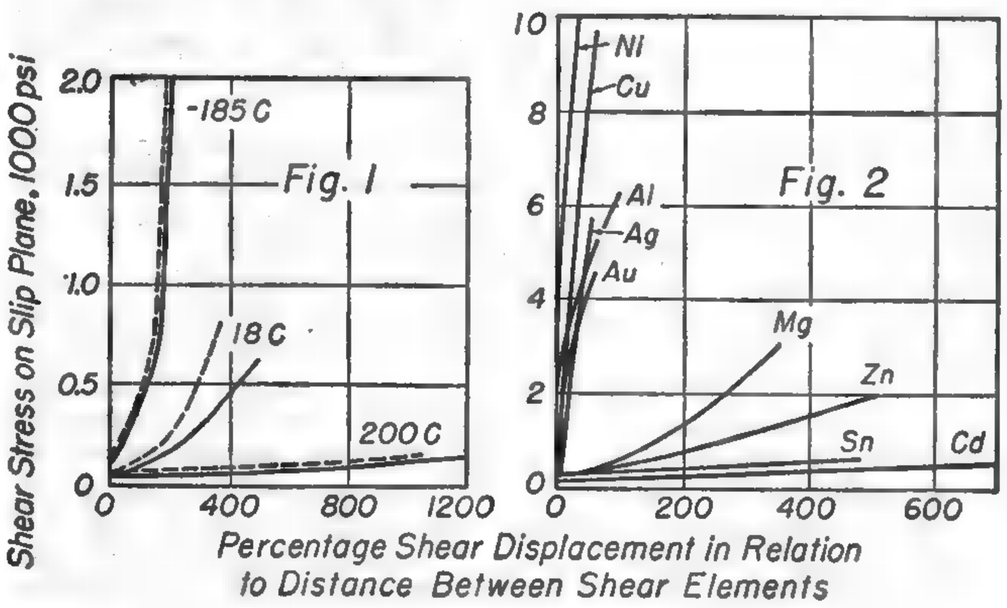

Fig. 1 Shear strengthening of single crystals of cadmium (Schmid and Boas[13])
Fig. 2 Shear strengthening curves of metal crystals (Schmid and Boas[14])

rate of loading has little effect on the strain hardening. In an intermediate region of temperature, which undoubtedly corresponds to the temperature at which ordinary softening and recrystallization begin in severely strain hardened polycrystalline material, much or little recovery may occur, depending on the rate of loading; and the final strain hardening of the metal varies according to these conditions. In the present example, after a shear of 400% at the higher rate, the crystal has a resistance of about 850 psi to further shear, and after the same amount of shear at the slower rate, a resistance of about 425 psi.

Curves of resolved stress versus shearing deformation for loading at room temperature have been obtained for the majority of common metals, as shown in Fig. 2. Since the slope of such curves is governed by the amount of recovery during the test, it appears that the tendency of the metals to recover from the effects of strain hardening during deformation at ordinary temperature, decreases in the following order: (1) cadmium, tin, (2) zinc, (3) magnesium, (4) gold, aluminum, silver, (5) copper, (6) nickel. Recovery in these single crystals does not signify recrystallization, which, however, may be expected to accompany the recovery process at high (hot working) temperatures when, with increasing deformation, crumpling or nonuniform distortion of the crystal becomes too severe to permit a reversion to the unstrained condition without complete reorganization of the grain structure. This condition is attained rapidly in polycrystalline material, which recrystallizes even after a small amount of deformation. Such inequalities of deformation exert only a secondary influence on the amount of strain hardening, and at a temperature of full recovery the occurrence of recrystallization does not appear to add greatly to the softness attainable in the simple recovery process. It is evident that the metals of Fig. 2 exhibit a decreasing tendency to soften or recrystallize after cold work in the order stated; that cadmium and tin would recrystallize at ordinary temperature, zinc and magnesium at not greatly elevated temperatures, and the others at successively higher temperatures. The effective temperature of hot working would also increase in this order but in a commercial operation would have to be determined by trial.

Table I gives temperatures of recrystallization after severe cold deformation, and favorable hot rolling temperatures of the commercially pure nonferrous metals.

Table I. Softening and Hot Rolling Temperatures of Nonferrous Metals

Metal	Effective Softening Temp, deg Fahr, After Severe Cold Deformation[a]	Best Approx Hot Rolling Temperature, deg Fahr (for Softness) [b]
Lead	Approx room temp	Somewhat above room temp
Tin	Approx room temp	Somewhat above room temp
Zinc	200[15]	350
Magnesium	200 +[c]	650[16]
Aluminum	525[17]	950[18]
Copper	700[19]	1550[19]
Nickel	1400 max[21]	2200[20]

(a) Approximate complete softening after one hour
(b) This means in general the highest temperature for satisfactory operation. Special requirements of mechanical properties are met by rolling at lower temperatures.

Slush Casting

By G. L. Werley* and G. O. Hiers*

OF ALL the metal casting processes in general commercial use, slush casting is probably the least known. The process has little competition from other methods of fabrication and its field is a restricted one, limited to the production of hollow castings. Also, only zinc-base or lead-base alloys are commonly used for casting by this process. Of the two types, the zinc alloy castings greatly predominate in tonnage.

Slush casting is the name given to that process in which molten metal is poured into a split mold (generally made of bronze) until the mold is filled; then, almost immediately, the mold is inverted and the metal that is still liquid is allowed to run out. The time required for this casting operation is sufficient to freeze a metal shell in the mold, corresponding to the shape of the cavity wall. The thickness of the wall of the casting depends on the time interval between the filling and the inverting of the mold, as well as on the chemical and physical properties of the alloy and the temperature and composition of the mold. However, skilled operators regularly produce good castings with remarkable uniformity in weight.

Zinc Alloys. The zinc alloys used for slush casting are of two classes: the aluminum-zinc type and the aluminum-copper-zinc type. The aluminum-zinc alloy usually has a nominal composition of 5.5% Al with the remainder Special High Grade zinc. Because this alloy is readily slush cast, producing very thin walls, its use is popular from the standpoint of initial cost. However, unless the impurity limits are rigidly controlled, castings made from this alloy are susceptible to subsurface network corrosion and premature failure by warping and cracking. Small variations in the aluminum content are not critical, except that they slightly affect the slushing characteristics of the alloy and consequently prevent the production of thin-walled castings. However, with the eutectic composition of 5.0% Al, it is almost impossible to produce slush castings, since one of the requirements of a slush casting alloy is that it must not have a single solidification point but must have instead an appreciable slushy range between the liquidus and solidus temperatures.

The second class of zinc alloys has a nominal composition of 4.75% Al and 0.25% Cu with the remainder Special High Grade zinc. Alloys of this class produce castings with improved mechanical properties and also with longer service life resulting from the protective effect of the copper addition. Slush casting this type of alloy is more difficult and produces castings with thicker wall sections. Therefore, the initial cost of the castings is generally greater than that for like castings made from the copper-free alloy. It is important to keep the composition of the Zn-Al-Cu alloy under close control since increases in the aluminum content above 4.75% approach the eutectic composition, which is not desired. Decreases in the aluminum content tend to make the alloy too sluggish for slush casting. The copper addition must be sufficient to afford the degree of durability desired but should not exceed an amount that would affect production seriously by causing excessive weight in the castings.

Lead Alloys. The lead alloy used for slush casting is close to the antimony-lead eutectic alloy in composition. Other elements are added to improve both the casting qualities and the grain refinement. A typical composition is 13.0% Sb, 1.0% Sn, 0.5% As, 0.1% Cu, and the remainder lead. The excellent resistance to corrosion of this alloy does not depend on the exact composition of the alloy. However, it is necessary to maintain rigid control of the composition, avoiding impurities which, even in small quantities, impair casting quality.

Finishing. Slush castings can be electroplated or finished with lacquers or baking enamels. However, baking temperatures should not exceed 300 F for the lead alloy nor 375 F for the zinc alloys.

Secondary Metals

By W. Bonsack* and D. L. Colwell*

THE DISTINCTION between "primary" and "secondary" metals and alloys is usually rather artificial, and therefore not entirely logical. The term "primary" should apply to metals derived directly from ores, and "secondary" to metals and alloys made from scrap and residues. However, there are so many combinations of these types of metals that no line can divide them sharply. Furthermore, in the production of many metals no distinction is made as to the source.

Common nonferrous alloys of copper, lead, tin, nickel, zinc, aluminum and magnesium are regularly produced from scrap and residues, diluted with pure metals when necessary. Many of these metals are called secondary and many are not, according to the principal product of the producers. Other rarer nonferrous metals, such as gold, silver, platinum, mercury and their alloys, are also produced from scrap and residues, but no distinction is made between these and their counterparts produced from ore. The recovery of many ferrous alloys from scrap iron and steel is a necessity, and the whole ferrous industry uses iron and steel scrap as a principal component, yet the term "secondary" is not applied to these metals.

It is possible to separate many nonferrous metals from their alloying constituents and to produce a metal as pure as was originally produced from the ores. Often it is feasible and economical to do so, but frequently also, the costs of such separation would be prohibitive. Copper, for instance, may be separated from zinc, tin, iron and other alloying elements by fire refining and it may be further purified electrolytically so as to produce copper of high purity. In some instances, where the contamination is severe, fire refining is employed and the fire-refined copper is ordinarily used without further electrolytic purification. On the other hand, pure aluminum may be produced from badly contaminated scrap by dissolving the scrap in caustic soda, with chemical elimination of the contaminating alloying elements, and final precipitation of alumina and reduction to pure aluminum. This practice was general in Japan when the supply of bauxite was shut off by the submarine blockade, but such a procedure is decidedly uneconomical. The customary practice in the use of scrap metals is to make use of the base metal and its alloying ingredients by the careful segregation of the scrap and the subsequent production of alloys adjusted to the compositions of the scrap involved. The resulting alloys are commonly termed "secondary".

Because of the difficulty of perfect segregation of scrap, secondary alloys often contain more alloying elements than their primary counterparts. These elements may be harmful, beneficial, or neutral. If harmful, they must be either removed or diluted. When it is feasible, such elements are removed; when removal is impractical, dilution is used as the only means of reduction. In most instances these incidental alloying elements are beneficial and re-

* The National Smelting Company, Cleveland

moval is not necessary. The antimony and tin in lead alloys, the zinc and tin in copper alloys, and the copper and silicon in aluminum alloys, are almost always beneficial in the production of the new alloy. Even when the alloying element is neutral, an ingot of improved characteristics often results from the use of prealloyed scrap, because better alloying is possible and dangers of segregation are lessened with each mixing and remelting. If a certain set of properties is required from a metal and these properties can be obtained only by the alloying of several other metals with the base metal, it is usually immaterial whether the alloying elements are already present in the base metal or whether they have to be added freshly; in fact, it is often helpful to have them already present. If two alloys are identical in composition, the properties of the alloys will be identical, unless their fabrication has introduced other variables.

Secondary metals and alloys have often been considered inferior because of their higher content of oxide. This may be true; however, some secondary metals are superior because of their lower oxide content. The amount of oxide present depends on the treatment the metals have received, and does not depend exclusively on the source of the metal. Many primary metals are refined from oxide ores or concentrates, and many secondary metals have become oxidized excessively during previous use or treatment. This oxide content may or may not be removed in the production of the ingot. Refining, fluxing and cleaning methods used in ingot production should be such that the oxide content is not excessive either in primary or in secondary ingot.

Price differentials between primary and secondary metals fluctuate with supply and demand. When the supply of secondary metal is plentiful and the demand low, the difference becomes substantial, making it more economical to use secondary metals wherever possible. When demand is high, the price difference decreases, and under unusual circumstances a few of the secondary metals have commanded temporarily higher prices. In 1941 pure secondary aluminum brought a higher price than pure primary aluminum, and even the common No. 12 aluminum alloy sold for the same price as pure primary aluminum.

For metals that are not plentiful or for which the price margin between primary and secondary is narrow or nonexistent, the distinction between primary and secondary is lost. There is good justification, therefore, for considering that the distinction between primary and secondary is commercial and not necessarily metallurgical.

In general, the reclamation of metal from scrap and residues varies, depending on the base metal concerned. Following are comments on the principal nonferrous metals commonly used in secondary form.

Aluminum. When aluminum and aluminum alloys are recovered, their compositions are usually the same as they were originally and, wherever possible, they are used again as such. The tremendous expansion of the aluminum-producing industry during the war, coupled with the severe shortage of aluminum while this expansion was being developed, necessitated an urgent program of segregation of alloy scrap in aluminum fabricating plants. Quantities of this scrap were remelted into secondary pig of the wrought alloy composition and were rolled or extruded directly into the wrought forms, either with or without further additions of pure aluminum. Many consumers of such "primary ingot" never recognized the fact that their supplies were actually largely secondary.

Where aluminum scrap has been less carefully segregated or where accidental mixing of alloys has occurred, the scrap is remelted and the composition of alloying metals is adjusted for the production of the kind of ingot used in aluminum castings. Such ingot is commonly used for the production of aluminum castings, either by sand-casting, permanent mold or die-casting processes. During the war certain alloys were developed for the production of castings in order to make best use of the high-grade scrap that accumulated constantly in the aircraft industry. Prominent examples are the die-casting alloys SC2, SC5, SC6 and SC7, and the sand-casting and permanent mold casting alloys SC8, SC42 and SC21 of the American Society for Testing Materials.[3] The careful wartime control of aluminum scrap made this ingot even more desirable than before the war, because alloying elements and impurities could be more carefully regulated.[4]

Aluminum is different from other nonferrous metals in being suited for large destructive uses in which the presence of impurities is not particularly harmful. Aluminum is used in the deoxidation of steel in amounts which, though small for the steel industry, are large for the aluminum industry. It is also used for the production of aluminum salts such as anhydrous aluminum chloride, and for the production of ferro-alloys by the thermit process. The one impurity most troublesome in the fabrication of both wrought and cast aluminum products is iron, and this impurity is entirely neutral when the aluminum containing iron is used in ferrous alloys. All these applications permanently destroy the aluminum for further metallurgical use, and it is by these destructive uses that the badly contaminated grades of scrap are consumed.

Some indication of the increase in quantity of secondary aluminum produced is given in Table I for the years 1942, 1943 and 1944. Particularly noteworthy is the increase in the amount of such aluminum used in wrought products shown in the same table.

Table I. Aluminum Recovered from Scrap and Residues, 1942, 1943 and 1944[5]
(In short tons)

	1942	1943	1944
Secondary aluminum ingot.....	144,694	196,373	214,879
Aluminum in wrought products.....	53,080	121,827	116,582

Copper. Copper is used largely as a conductor for electricity. Its conductivity is very sensitive to small amounts of alloying elements; consequently, secondary copper is seldom used for this purpose. The brass industry also consumes large quantities of copper, and here again, particularly during the war when most brass was cartridge brass, only primary copper was used.

Scrap copper wire and scrap wrought brass are excellent base materials for the production of copper alloy ingot for castings, and most of the cast brass and bronze products used in this country are produced from such so-called "composition ingot". This ingot is made by the blending of the proper grades of brass and bronze scrap so as to secure the required amounts of zinc, tin and lead in the resulting alloy.

In certain instances where copper alloy scrap contains too many alloying elements for the most economical use, the common procedure is to smelt the scrap in a blast furnace, recovering the copper and nickel and burning off the tin, lead, iron and zinc. These alloying elements may or may not be recovered in a baghouse as dust or as oxides. Such fire-refined copper is suitable for use in many brasses and bronzes, and if desired, may be further electrolyzed to produce copper indistinguishable from that electrolyzed from ores.

One of the important measures for conserving copper during the war was the "down-grading" urged by the War Production Board in order to promote the use of secondary alloys. A complete chart was issued showing which alloys it was possible to use as alternates for alloys containing high proportions of primary copper and tin. It was found that many parts normally made from copper-tin alloys of high purity (such as Navy G, 10% Sn) could be produced satisfactorily from other alloys made from ingot with a higher proportion of scrap. The down-grading was from Navy G to Navy M to ounce metal (85-5-5-5) to valve metal (81-3-7-9) to manganese bronze to leaded manganese bronze. Each step used a higher proportion of copper-base alloy recovered from scrap, and not only was copper conserved, but experience indicated that in one instance after another the "lower" alloy was as serviceable as the alloy formerly used and was more economical as well. The criterion of substitution was the minimum permissible copper content compatible with the service requirements of the final product. Secondary copper filled many needs for bronze or brass where it had been believed formerly that virgin material was essential.

The recoverable copper content of copper-base scrap

consumed in 1941 is indicated in Fig. 1.[2] In 1944 the production of primary copper was 1,250,000 tons, and an additional 950,000 tons of copper was recovered in brasses and bronzes and used as such and almost 100,000 tons of pure copper recovered as copper. This proportion is abnormally high because of the huge amount of cartridge brass produced in 1944, but it illustrates the important role played by secondary copper.[1]

Lead. Lead is often considered indestructible, and its recovery from storage batteries, solders, type metals and cable coverings, supplies a large proportion of the lead used in producing more of those same products. The antimony content of such products is also recovered and often the antimonial lead so produced is superior to that made from primary lead and antimony, because alloying is better.

Methods of recovery of the lead from storage batteries, solders, type metals and cable coverings is similar to that used for the recovery of tin. The metals are sorted and melted with proper fluxing and cleaning, and composition is adjusted to meet the requirements. The use of antimonial lead in storage batteries is the largest single application for lead and a considerable part of such antimonial lead is secured from secondary sources.

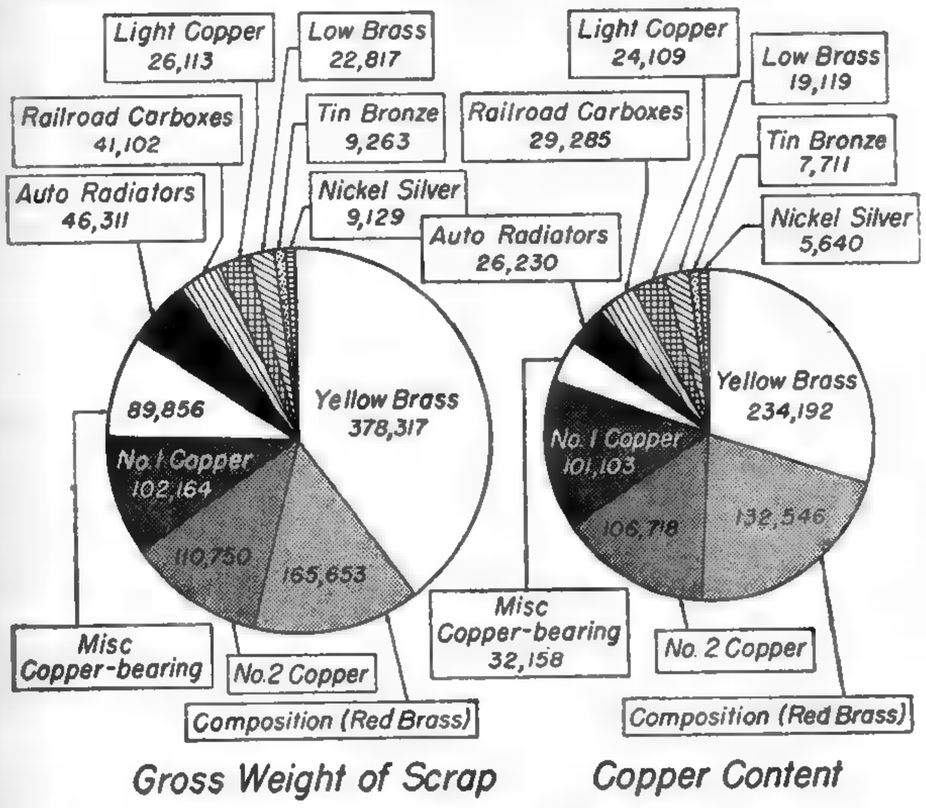

Fig. 1 Recoverable copper content of copper-base scrap consumed in 1941, in tons of 2000 lb (Wright[2])

The lead content recoverable from lead-base scrap in 1941 is illustrated in Fig. 2.[2] During the last ten years secondary lead has been used at the rate of about 300,000 short tons annually.[1] The annual production of primary lead and antimonial lead was only about 450,000 short tons during the same period.

Magnesium. The magnesium industry is comparatively new; consequently the recovery of magnesium scrap has not settled into a definite pattern. More magnesium is used in the cast form than in wrought products, so scrapped magnesium castings may be reclaimed easily for casting alloys. Wrought forms of magnesium may also be reclaimed for casting alloys, but the amounts of wrought scrap available are comparatively insignificant. The reclaiming of magnesium from the more finely divided forms, such as borings, turnings, grindings and drosses, is more difficult than with other nonferrous metals because of the combustibility of such finely divided forms. If the scrap is not too fine it may be used in the production of casting ingot, just as are scrap castings of magnesium. In some instances fine scrap may be used for the addition of small amounts of magnesium to alloys of other metals, as in introducing magnesium into aluminum alloys, or such scrap may be diverted to chemical uses.

The consumption of various forms of scrap magnesium in 1944 was, as follows:[5]

Cast scrap	1,706 short tons
Solid wrought scrap	129 short tons
Borings, grindings, drosses, other	15,179 short tons

It is significant that, of this quantity, 13,370 tons was put into magnesium alloy ingot of various compositions and only 541 tons into chemicals.

Nickel. Nickel used as sheet and in anodes for electroplating can easily be recovered for nickel additions to either ferrous or nonferrous alloys.

Nickel is also a major ingredient of monel metal, nickel silver and certain nickel brasses. From such alloys it is usually recovered with the copper, either by fire refining or by melting and adjusting the composition. The nickel content of such a product is a prime consideration in the production of composition ingot from copper alloys, because nickel is more expensive than any of the common nonferrous metals, with the exception of tin.

Although the world production of nickel for 1944 was 179,000 short tons,[5] only 4321 tons of secondary nickel was recovered in this country in 1944.[5] Of this quantity, the major portion (2994 tons) was in nickel-base and copper-base alloys, and only 410 tons in chemicals.

Tin. Tin is one of the least plentiful of the common nonferrous metals and that used in the United States is almost all imported. Tin is also the highest priced of the common metals, and consequently it has been recovered eagerly and reused wherever possible.

The chief applications for tin are in tin plate, solder, bronze and babbitt, in that order, although this normal relationship was disturbed during World War II. Methods of recovery vary with the product. The detinning of tin plate is not normally economical, although during the war a considerable quantity of pure tin was recovered by this process. The reduction in the quantity of tin used in tin plate made detinning a more and more expensive process per pound of tin recovered, and the practice probably will not continue to a great extent when pure tin becomes available again.

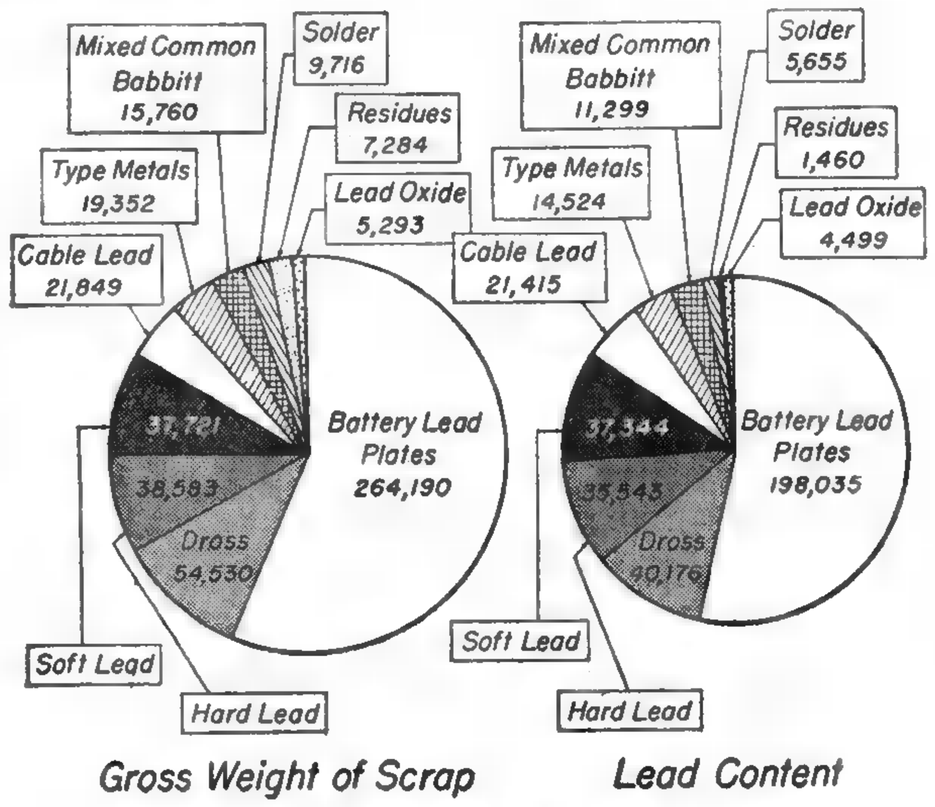

Fig. 2 Recoverable lead content of lead-base scrap consumed in 1941, in tons of 2000 lb (Wright[2])

Solders, babbitt metals and collapsible tubes often contain very high percentages of tin. It is a simple matter to sort these roughly according to tin content, and then to remelt them with proper cleaning and fluxing. The resulting product contains varying quantities of lead and antimony, and is usually free from other metals. It is therefore an excellent base for the production of lead-tin solders or bearing metals that contain lead as well as tin. Collapsible tubes and other pure tin products, such as tin pipe, are an excellent and normal source of tin for solders and bearing metals. During the war there was an extensive drive to collect all such tin-bearing scrap; consequently very little primary tin was used for solders and bearing metals.

Bronzes and many brasses require tin, and quantities of scrap bronzes and brasses are diverted to the production of the necessary tin-bearing copper alloys, because tin is the most expensive common metal normally used in brasses and bronzes. Many of the reclamation processes of these

copper-base alloys are built around the maximum use of the tin content.

The consumption of primary tin in the United States is normally from 40,000 to 100,000 long tons annually. During the war years the tin recovery in this country, as reported by the Bureau of Mines,[1] amounted to about 30,000 long tons annually; in time of peace about half this amount of secondary tin is normally produced.

Zinc. The two largest uses for zinc are in galvanizing and in brassmaking. The zinc used in galvanizing is sacrificially consumed in the protection of the iron and steel, since these are more susceptible to corrosion. Therefore no great amount of zinc is recovered from galvanized ware. The zinc used in brassmaking is normally recovered in the secondary brasses and bronzes, as described under Copper above. The relatively small portion of the domestic production of zinc that is used as pure zinc, appears mainly in the form of sheet. Much of this can be and is recovered from clippings, discarded dry cells and such, and is used in making zinc additions to brasses and bronzes.

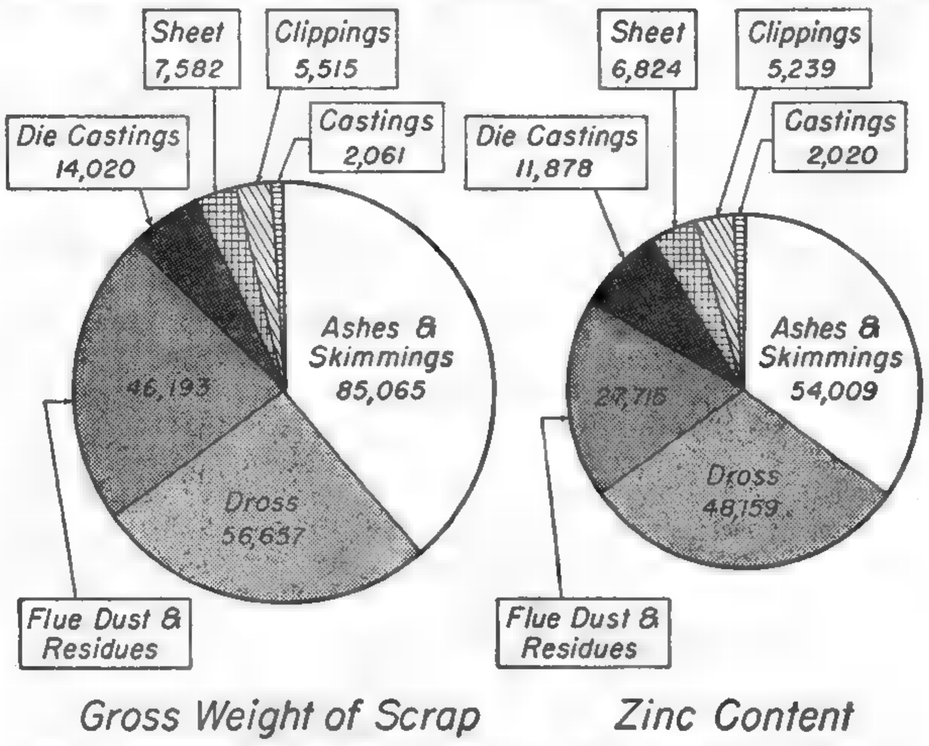

Fig. 3 Recoverable zinc content of zinc-base scrap and residues consumed in 1941, in tons of 2000 lb (Wright[2])

The only zinc-base alloys commonly employed in considerable quantities are those used for die castings and slush castings. Such alloys contain from 90 to 96% Zn with aluminum, magnesium and sometimes copper, and are extremely sensitive to minute amounts of tin and lead when present as impurities. Consequently, only special zinc of high purity is used in their manufacture. Scrap die castings are considered unsuitable for the production of zinc casting alloys of high quality. Instead such scrap is ordinarily used to produce zinc dust or oxide, or to provide the zinc content of other alloys. The zinc that is recovered and used as zinc is principally that redistilled from ashes, drosses, skimmings, baghouse dust and other residues. Although appreciable, the amounts thus recovered do not constitute a large proportion of the domestic consumption of zinc. The recoverable zinc content of zinc-base scrap and residues in 1941 is indicated in Fig. 3.[2]

Low-Melting Alloys

By Walter C. Smith*

THE TERM "low-melting metal" is sometimes used to describe type metals, lead-tin solders and lead-antimony alloys, but generally the term is applied to alloys that melt at temperatures below 450 F (233 C). The low-melting or fusible alloys are the binary, ternary, quaternary and quinary mixtures of bismuth, lead, tin, cadmium and indium or other metals.

Melting Temperatures. The melting temperatures of the several component metals of the fusible alloys are listed in Table I.

Table I. Melting Temperatures of Component Metals of Fusible Alloys

Metal	Melting Temperature, deg Fahr	Melting Temperature, deg Cent
Lead	621	327
Cadmium	610	321
Bismuth	520	271
Tin	449	232
Indium	313.5	156.4

The eutectic alloys that are produced from these metals and that are of interest as low-melting alloys, are shown in Table II.*

In addition to the eutectic alloys, hundreds of noneutectic alloys have been made and their freezing ranges have been determined. Many noneutectic alloys have been used under conditions where the eutectic alloys are not suitable. All the noneutectic alloys melt over a range of temperature, rather than at constant temperature. The "let go" temperatures vary with the methods of testing, the shape and mass of the alloys, the location in the apparatus, the loading applied to the alloys, the rates of heat input, and other factors. The low-melting alloys are usually rated according to their "yield" temperature, as determined under test conditions established by the Compressed Gas Manufacturers Association, New York, December 17, 1936.

Table II. Compositions and Melting Temperatures of Eutectic Fusible Alloys

Melting Temperature, deg Fahr	Melting Temperature, deg Cent	Composition, percentage Bi	Pb	Sn	Cd	Other
478	248	....	82.50	....	17.50	....
430	221	....	....	96.50	....	3.50 Ag

Table III includes compositions and both melting and yield temperatures for a few of the noneutectic alloys that are being used currently.

Physical and Mechanical Properties. In general the low-melting alloys that contain less than about 48% Bi shrink

* Metallurgist, Cerro de Pasco Copper Corporation, New York

* In technical and trade publications, the low-melting alloys have been designated by a variety of names. This practice has resulted in many confusing and contradictory statements. For example, a review of the literature will disclose at least eight different alloys designated "Wood's Alloy" and four designated "Anatomical Metal". One alloy of bismuth, lead and tin can be found under three different names. The names of alloys are omitted purposely from the present article, in order to avoid further confusion.

during solidification; those containing 48 to 55% Bi exhibit little change of volume; and those containing more than 55% Bi expand during solidification. Bismuth alloys that contain 33 to 66% Pb, even when moderate amounts of other metals are present, usually exhibit growth after solidification and during aging. Many of the low-melting alloys follow the laws of thermal contraction during cooling from solidification temperature to room temperature. Some show shrinkage for the first few minutes after solidification, and then start growing rapidly; other low-melting alloys shrink during cooling to room temperature

Table III. Compositions, Yield Temperatures and Freezing Ranges of Some Noneutectic Fusible Alloys

Temperature, deg Cent		Composition, percentage				
Yield	Freezing Range	Bi	Pb	Sn	Cd	Others
159	175 to 145.....	12.60	47.50	39.90	....	....
154	163 to 143.....	14.00	43.00	43.00	....	....

72.5	90 to 70.....	42.50	37.70	11.30	8.50	....

and the growth does not begin for 30 min to 3 hr after the alloy has reached room temperature; still others exhibit no shrinkage and grow rapidly while still warm. Approximately 90% of the growth occurs during the first 12 to 24 hr after casting, but some low-melting alloys continue to grow at reduced rates for 500 to 1000 hr after casting. Rapid cooling or quenching of the alloys that exhibit growth, ordinarily increases the rates of growth, but does not affect final growth values. The total growth varies from 0.0001 to as much as 0.007 in. per in. and is governed by the composition of the alloys. The fusible alloys range in hardness from about 5 to as high as 22 Bhn. The tensile strength ranges from 3000 to 13,000 psi and the elongation from 0 to 300%, depending on the composition of the alloy. All the fusible alloys creep at room temperature under relatively light continuous loads.

Uses of Low-Melting Alloys. Before 1930 only a small proportion of the world's bismuth consumption was used in the manufacture of the low-melting alloys. Then the use of these alloys was expanded so rapidly that during World War II the War Production Board had to place them under rigid allocation to insure proper distribution to the essential war industries.

Low-melting alloys are used in:

Ammunition composites
Fire-detection apparatus and alarm systems
Safety plugs for tanks and cylinders for compressed gas
Fusible elements in automatic sprinkler-heads and fire-door release links
Automatic shut-offs for gas and electric water-heating systems
Constant-temperature baths for autoclaves and for tempering
Liquid seals for bright-annealing and nitriding furnaces
Low-melting solders
Forming and stretching dies in aircraft construction
Spotting, erection and checking fixtures for automobile and aircraft construction
Filler for thin-wall tubing and molding that is being bent
Production of accurate patterns
Cores on which copper, iron, nickel and other metals are electroformed
Anchoring dies, punches, machine parts, magnets and ceramic parts
Chucks for holding irregular or delicate parts during machining operations
Coating for wood patterns, core boxes, and the like
Models for engraving machines
Proofcasting of forging dies, plastic molds and other irregular cavities
Selenium rectifiers, as the counterelectrode
Molds for wax models for precision casting
Models in place of wax for large precision castings
For addition of lead and bismuth to aluminum and other metals and alloys to obtain free-cutting materials

Bearing Materials

By the Subcommittee on Bearing Materials*

A BEARING is a machine element designed to transmit loads (or reaction forces) to a shaft rotating relative to the bearing. *Journal bearings* are cylindrical (full cylinders or segments of cylinders) and are used when the shaft load (or reaction force) is essentially perpendicular to the axis of the shaft. *Thrust bearings* are ring-shaped (full rings or segments of rings) and are used when the shaft load is in the direction of the axis of the shaft.

Function, Design and Manufacture of Bearings. When the load has both an axial and a perpendicular component, sometimes *flange bearings* are used. They are, in effect, a combination of journal bearings with one (single-flange) or two (double-flange) thrust bearings.

Characteristic of all plain bearings is the sliding movement of the shaft (or thrust collar) surface with respect to the bearing surface, in contrast with bearings that have rolling contact. In order to reduce the friction that results from this sliding movement the bearings are lubricated with oil or grease. Under best conditions of operation, particularly at high sliding speeds, a continuous layer of lubricant should be maintained between the sliding surfaces. Suitable lubrication, essential for satisfactory bearing operation, can be achieved only through judicious design of the bearing. One factor of great importance in this connection is the *clearance* between the bearing and the shaft. Oil *grooves* are often provided at the bearing surface to help in the uniform distribution of the available oil over the whole bearing surface.

Under ideal conditions of lubrication a continuous oil film would be maintained between the sliding surfaces; consequently the material of the bearing surface would be quite unimportant. However, under actual conditions of bearing operation, some direct contact between shaft and bearing surface is unavoidable. As a result, the "bearing qualities" (*see below*) of the material forming the bearing surface are actually of paramount importance, particularly where sliding speeds are high. Also, the various bearing materials show considerable difference in their ability to maintain a continuous oil film at their surface. The term "oiliness" (of a bearing material) expresses the tendency of the oil to form a tenaciously adhering film at the bearing surface.

A common cause of failure in bearings is the breakdown of the oil film. This results in direct contact between shaft surface and bearing surface, and in greatly increased friction. Under such conditions, the wear of the bearing surface—and often of the shaft surface also—is excessive. The increased friction may finally lead to seizure, or the heat generated may melt the bearing alloy. The most frequent causes of seizure (*see* Antiseizure Characteristics, *below*) include overloading, failure of the oil supply, or a decrease in the oiliness of the bearing material in the course of continued service. The oiliness of the material decreases, for example, in copper-lead bearings, if the conditions of operation cause selective corrosion of the lead, leaving the bearing surface deleaded.

In the large majority of bearings used at present, the bearing material itself is a metal or an alloy. For special applications, such as rolling-mill bearings, nonmetallic bearings are being used successfully. Typical bearing alloys that have excellent *antiseizure characteristics* and can be used at high sliding speeds, are the tin-base and lead-base babbitts and cadmium-base bearing alloys, all relatively soft. To improve their load-carrying capacity, these alloys

*The members of this Subcommittee are O. W. Ellis, *Chairman*, (Ontario Research Foundation), Paul A. Beck (University of Notre Dame) and Arthur F. Underwood (Research Laboratories Division, General Motors Corporation).

must be supported by a bearing shell made of stronger material. Bearing shells are usually made of steel or, in some instances, of bronze.

A good, mechanically strong bond between the bearing alloy and the supporting shell is very important for best performance. Until quite recently, unbonded or poorly bonded babbitt liners were cast thick so that they could be machined to finish with a thickness of ⅛ to ¼ in. or more. It is probable that the practice of using relatively thick linings, well bonded however, will persist where bearings are subjected to substantially steady loads; for example, railroad journal bearings. (*See* Lead-Base Alloys, *below*.) An important recent development is the bearing with well-bonded liner about $\frac{1}{64}$ in. thick. Decreasing the thickness of the soft layer of bearing alloy, results in considerable improvement in the load-carrying capacity. The thinner layer, when well bonded to the steel back, has much less tendency than the unbonded heavy layer to be squashed out under heavy loads. Also, in alternately

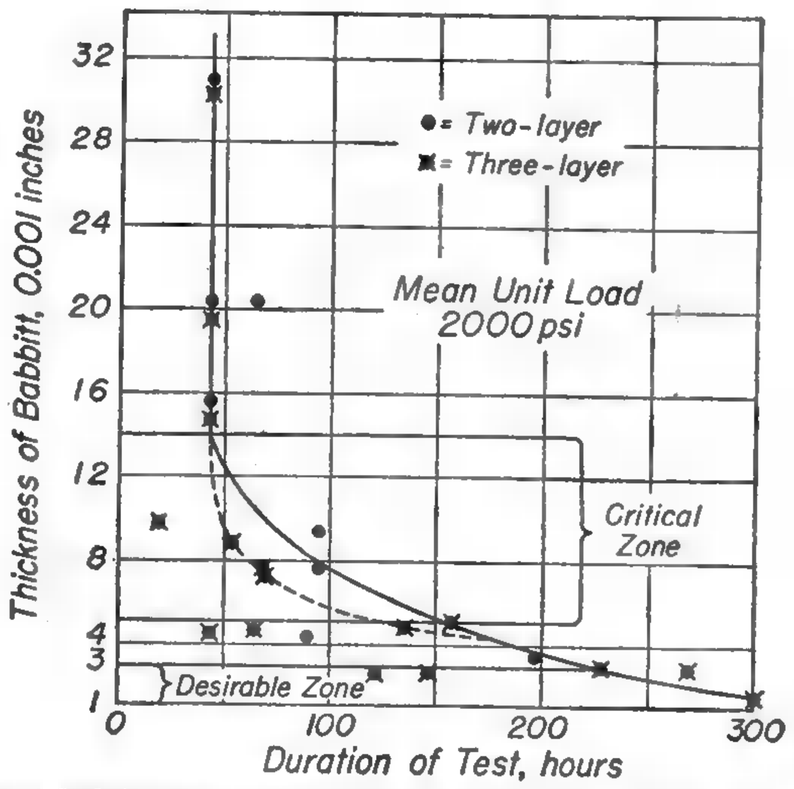

Fig. 1 Relationship between bearing life and babbitt thickness for two-layer and three-layer bearings (Luetkemeyer[7])

loaded applications, the bearing fatigue strength is increased considerably (*see* Fig. 1). A typical thickness of bearing alloy layer in automobile connecting-rod bearings, as now made, is 0.016 in. Thinner layers, down to 0.002 in., are used increasingly with great success. With both types, the bearing alloy is usually bonded to a steel back about 0.040 to 0.120 in. thick (*bimetal bearings*). Recently, electroplated layers about 0.001 in. thick have been introduced and proved to have greatly increased bearing fatigue strength. Such thin layers, however, wear off easily under unfavorable operating conditions. For this reason they are usually not plated directly on the supporting steel back; for safety a stronger intermediate layer of bearing alloy is used. This construction combines the excellent antiseizure characteristics of the babbitt bearings with greatly increased load-carrying capacity.

Formerly all babbitt connecting-rod bearings, as well as most other babbitt bearings, were cast into place as full bearings. This method is still used in many applications, but the large majority of all automotive bearings are manufactured at present in the form of half bearings by the blanking, forming and broaching of continuous bimetal strip. For all strip-type babbitt bearings and most strip-type copper-lead bearings the continuous bimetal strip is produced by casting the bearing alloy on a steel strip. However, a considerable number of automotive bearings are now being manufactured by sintering a purposely porous layer of copper and nickel particles to a continuous steel strip, and then casting a Pb-Sn-Sb alloy on it in such a way as to allow the penetration of the lead alloy into the pores of the sintered layer, and to cause the formation of a lead alloy overlay on top of it. The sintered porous structure, bonded to the steel backing, serves as a bonding medium and a supporting structure for the lead-base bearing alloy.

The resulting strip is then processed further as described above. Still another method recently developed involves the use of bimetal strip made by sintering copper-lead alloy on one or both sides of a steel strip.

Aircraft bearings are made, to a large extent, as full bearings by the casting of the copper-lead alloy or by the electroplating of the silver layer inside a cylindrical steel shell. For casting full bearings, both gravity casting and centrifugal casting methods are in use. Solid bronze bearings, without steel backing, are machined from hollow cylindrical castings or from bronze tubes.

Survey of Bearing Applications. Bearings are used in various types of machinery, under conditions so widely different that the properties required of bearing alloys cover a very broad range. A bearing alloy well suited for a certain application may be entirely useless in another. A good bearing alloy cannot be defined in a general way, but must be determined according to the type of application. The factors to consider in appraising a specific bearing application are rather numerous. Some of the most important are the following:

Type of Load. In the bearings of electric motors with belt drive, the load is essentially steady; that is, it does not change in direction. In applications like railroad-car journal bearings, the resultant force on the bearing changes in direction with the movement of the car, and is affected also by braking and other conditions experienced in operation. However, the changes in direction of the resultant force on these bearings are relatively minor in comparison with those on the connecting-rod bearings of reciprocating internal-combustion engines or the master-rod bearings of radial-type aircraft engines, which are alternately loaded. The load-carrying capacity of alternately loaded bearings is usually determined by the "bearing fatigue strength" of the bearing material used. In steadily loaded bearings this property is of no importance.

Amount of Load. It is important to know what shaft load the bearing is expected to support. High steady loads require relatively hard bearing alloys, such as leaded bronzes. Alternating loads up to approximately 1200 psi are considered low and can be supported by ordinary babbitt bearings but are about the maximum that can be supported. Thin babbitt linings can take loads up to approximately 1400 psi. The limit of alternating load for ordinary copper-lead bearings is about 1600 psi. With three-layer bearings that have a steel back, a 25% Pb copper-lead intermediate layer and a plated lead overlay it is considered allowable to load as high as 3000 psi, with a reasonable life expectancy for automotive and Diesel engine applications, if other conditions are favorable.

The above figures for the alternating loads that can be sustained by various bearing materials are, of course, not to be taken as fixed maximum loads, but only as approximations. The individual bearing applications may have many variables affecting the maximum load that the bearing can sustain. These variables should be taken into consideration when the bearing is designed.

Speed. The sliding speed of the shaft surface against the bearing surface is significant. The bearing alloys best suited for high-speed operation are the babbitts.

Bearing Temperature. Both the strength and the corrosion rate of bearing alloys depend on the temperature. Where the operating temperatures are high, either normally or during emergencies, certain otherwise excellent bearing alloys cannot be used. Sometimes the melting of the bearing alloy limits the operating temperature. For instance, a lead-base bearing alloy that consists of lead plus calcium plus alkaline earth metals, may perform satisfactorily in a railroad-car journal bearing where an alloy of lead plus tin plus antimony, with lower solidus temperature, would melt out as a result of the rise in temperature caused by "waste grab".

Corrosive Conditions. Certain bearing alloys (such as tin-base babbitts) are much more resistant than others to the corrosive action of the acids contained or formed in the lubricating oils during operation. In some applications, where the corrosiveness of the oil cannot be decreased by the use of inhibitors, or otherwise controlled, the different corrosion resistances of the various bearing alloys may be the decisive factor in selection.

Type of Oil Supply. The amount of oil available in the bearing, and the reliability of the oil supply depend to a great extent on what type of lubrication the design requires. For instance, with wick lubrication a bearing alloy of much better "emergency running qualities" is required than with the more reliable forced-feed lubrication.

Dirt Conditions. A railroad-car journal bearing operated in the desert suffers much more wear than otherwise because of the abrasive effect of sand particles that find their way into the bearing. A certain amount of dirt can be embedded by a soft bearing alloy like babbitt and thereby rendered relatively harmless. Conversely, an otherwise desirable bearing alloy with less embeddability may be unsuited for use where dirt is present.

Shaft Hardness. Harder bearing materials require harder shafts. Babbitt bearings may be used with soft steel shafts, but copper-lead bearings will cause excessive wear of the shaft unless the hardness of the surface of the shaft is at least 250 Bhn.

Properties Required of a Bearing Material. A bearing material may have to withstand a variety of imposed conditions. The relative importance of the properties of the bearing will change from one application to another. Thus, severely corrosive conditions will determine the choice of metal in a certain application, whereas requirements of fatigue strength will necessitate a different material for another installation. The following order of discussion does not indicate relative importance.

Resistance to Fatigue. The fatigue life of a bearing material is likely to be the most important characteristic for conditions of alternating load. As in steel parts, fatigue is cumulative and the fatigue failure of a bearing may occur after many millions of cycles of satisfactory operation. However, in contrast with steel, for example, the endurance limit for a bearing metal in a specific application is not so well defined, because so many factors influence this limit. When a bearing is failing by fatigue, the effective area decreases gradually until the remaining surface will not support the load. Then sufficient heat is generated to cause burning out, or seizure.

The fatigue resistance of a bearing metal is properly tested under operating conditions or by a method that reproduces operating conditions. The results of tests made in devices such as rotating-beam test machines, in which specimens are subjected to bending stresses, do not necessarily indicate the probable life of bearings in service. Resistance to bearing fatigue is a property distinctly different from the usual fatigue resistance.

Formerly, fatigue failures were universally blamed on poor bond between the bearing metal and its backing. It is now recognized that fatigue cracks start at the bearing surface and work down almost to the bond surface between bearing alloy and steel back. Then the cracks are propagated parallel to the bond surface, but just above it, leaving a minute layer of bearing material attached to the steel or bronze. As the cracks progress, they separate the metal into "loose tiles" that may be eroded away.

Temperature is of varying importance with different materials. Alloys of the "white metal" class have fatigue life greatly increased as the operating temperature of the bearing is decreased. Under certain conditions of high operating temperature, a babbitt bearing will have twice the fatigue life when the temperature is decreased 20 F. Copper-leads, cadmium alloys, aluminum alloys and, more especially, silver, are much less affected.

Since about 1936, improved production techniques have allowed the use of a decreasing thickness of the bearing metal. This has increased the fatigue limit, especially of white metals. The relative improvement for a tin-base babbitt is as follows:[7] (*See also* Fig. 1.)

Thickness, inch	0.030	0.020	0.010	0.005	0.003
Life, ratio	1	1	1.5	3.2	4.6

Considerable research has been done to improve the fatigue resistance of white metals by the addition of alloying elements. Although additions will develop an increase in such mechanical properties as hardness and compressive strength, they are ordinarily of little value in fatigue. As usual, there is no general rule in this matter; tin, for example, is effective in copper-lead.

Antiseizure Characteristics. This property can be the most important. If journals always ran on an oil film, there would never be metal-to-metal contact with the bearing surface. Then very hard bronze or even steel would be satisfactory. But under starting and stopping conditions, heavy load, high surface speed, or shaft deflection, the oil film may not be uniformly established, so the surface qualities are important. When two metals are rubbed together in contact, heat is generated, thereby raising the temperature of the surface. Ultimately the temperature is high enough to cause intermittent welding of the metals. If the energy available in the journal is sufficient, the junctures are torn apart. The bearing and journal are said to be "scored". If the welding is so severe that the machine is stalled, the term "seizure" is applied. Certain metals stand these extreme conditions better than others, and are said to have superior antifriction quality.

The rating of materials for this quality is based largely on experience, because of the complex sets of operating conditions. However, a general arrangement of popular metals would be, in order of decreasing ability, white metals, copper-lead, leaded bronzes, bronze (Table XIX).

At one time it was thought necessary for a bearing to have two constituents if it was to have the characteristics of good antiseizure quality. Experience now shows that this supposition is not true. Further mention of these observations will be made under Structure.

Bonding Ability. All commercial bearing materials can be well bonded to appropriate backings provided the correct procedure is followed. Details of proper cleaning and "tinning", where required, correct temperature and suitable quenching rate must be adhered to. Such information, in detail, can be obtained in publications that deal with bearings, in handbooks, and from the suppliers of casting babbitts. The casting of materials other than "white metals" usually involves relatively high temperatures and is done in special bearing plants.

Naturally, some metals have higher bond strengths than babbitts, for instance. But "poor bond" is relatively so rare that fatigue is usually the cause of a failure. A badly bonded metal will peel cleanly from its backing or will have an undesirable interlayer that can be detected by metallographic examination.

Compressive Strength. The compressive strength of bearing metals is important when the load (usually unidirectional) is heavy enough to cause extrusion. In white metals compressive strength decreases rapidly with increased temperature. All metals increase effectively in strength as the thickness is decreased; therefore, there has been ■ steady reduction of lining thickness, except where wear is ■ factor.

Unfortunately, there appears to be little correlation between compressive strength and fatigue resistance when considering ■ single class of material. For example, certain additions increase the compressive strength of tin-base babbitt, but do not increase the fatigue resistance.

Deformability. Some authorities include this property with antiseizure characteristics, and there is good reason to do so. "Deformability" is used here to cover two rather special requirements that are closely related.

Many bearing installations support shafts that are flexible with respect to the imposed load, so that the shaft deflects at a considerable angle when going through the bearing. Such a condition causes heavy bearing pressure at the ends of the bearing and leads to rupture of the oil film. This series of events often results in scoring and seizure in the end areas, ultimately causing complete failure. (With bad deflections, a narrow bearing may perform better than a wider one with lower loading in pounds per square inch.) But if the bearing material has the ability to yield sufficiently to take care of the misalignment, then trouble will not develop. In equipment, from punch presses to electric motors and automotive engines, this property can be of prime importance.

A second feature under Deformability is the ability to embed dirt. Here again the operating conditions vary from a totally enclosed refrigeration unit, where no dirt is ever present, to certain tractor applications. Some bearing materials will embed considerable quantities of dirt without seizure, whereas a bearing of another material will fail if

as little as 0.01 oz of sand is introduced. It is true that when the dirt is embedded, wear of the journal is likely to increase, but this is preferable to seizure. The grooving both of bearing and of journal surfaces frequently originates in dirt introduced by the oil. Hardness readings, in general, indicate the embeddability. Obviously dirt should be kept from a bearing, but this is not always possible.

Resistance to Corrosion. The corrosion of a bearing material depends on two factors—a corrosive lubricant and a bearing that is corrodible under the operating conditions. Without both factors, corrosion will not occur.

The corrosive lubricant can result from the addition of other compounds, such as animal or vegetable oils, to petroleum oils. Or, a petroleum oil may oxidize to form acidic products. In either instance, the acids are then available to attack any susceptible bearing metal by a chemical reaction.

Table I. Chemical Compositions of Tin-Base Bearing Alloys (ASTM B 23-46T)

Alloy Grade	Composition, percentage[a]					
	Tin	Antimony	Lead	Copper	Arsenic	Bismuth
1	91	4.5	0.35 max	4.5	0.10 max	0.08 max
2	89	7.5	0.35 max	3.5	0.10 max	0.08 max
3	83.3	8.3	0.35 max	8.3	0.10 max	0.08 max
4	75	12	10	3.0	0.15 max	.....
5	65	15	18	2.0	0.15 max	.....

(a) Other elements: iron, 0.08% max; zinc and aluminum not to exceed 0.005% when determined on a 10-g sample.

Pure or improperly alloyed lead, cadmium and copper are dissolved by certain of these acidic compounds. Under such conditions the bearing gradually disappears, with the development of increasing clearance that may lead to complete failure. When the metals are properly inhibited by alloying, there is no reasonable chance for corrosion. Only corrosion-resistant metals should be employed in installations where acidic oils may be present. Many bearing alloys susceptible to corrosion are used extensively, but the engineer must make sure that noncorrosive conditions continue.

Sometimes corrosion may attack the various constituents selectively. Thus a particular oil may attack the lead of a copper-lead bearing.

As in all chemical reactions, the activity increases rapidly with temperature. Instances are known where, at temperatures below 240 F, a given bearing is commercially satisfactory, but not at 280 F in the same application.

Structure. Certain chemical and metallurgical features will be discussed in this section without reference to crystal arrangement. It was believed at one time that two metallographic constituents, "hard crystals in a soft matrix", were essential to a bearing material. The fallacy of this view is well demonstrated by the current widely used practice of employing pure tin, lead, cadmium, silver and even copper, as a bearing surface. Tin, lead and cadmium are very weak and therefore are applied as thin layers (usually electroplated) where strength requirements are not high. Another disagreement with the "hard crystal" theory is indicated by copper-lead, which consists of islands of soft lead in a matrix of hard copper.

When heavier loads are to be supported, the material is strengthened by alloying elements. Or again, if a high-strength material such as copper or silver is used, the anti-seizure characteristics may be improved by the addition of lead. Therefore, most bearing materials do have two or more constituents. However, tnese constituents do not contribute to bearing performance in the manner postulated by the older theory. Rather, alloying additions are made in order to produce specific effects on the bearing properties desired in a particular application.

The crystal size, as shown by metallographic examination of polished specimens, is not important if kept within the limits easily produced by modern casting technique. A possible exception is lead-base alloy with appreciable arsenic content. Very slow cooling of all babbitt materials will produce large crystals, which tend to lower fatigue strength and which may cause a mottled surface after use.

Compositions and Properties of Bearing Materials

Tin-Base Alloys. The tin-base bearing materials, known commercially as "babbitt metals" or "babbitts", are substantially alloys of tin, antimony and copper, to which may be added as much as 30% Pb for the purpose of reducing their cost. Zinc, aluminum, arsenic, bismuth and iron should be limited in amount.

The compositions of tin-base bearing alloys, as published in ASTM Tentative Specification B 23-46T, are presented in Table I.

The compositions of tin-base bearing alloys, according to SAE specifications, are shown in Table II. It may be noted that the limits for chemical composition are closer for metal in ingot form than for bearings, because of the possibility of changes in composition as a result of casting.

Table II. Chemical Compositions of Tin-Base Bearing Alloys (SAE)

Element	Composition, percentage[a] [b]					
	SAE 10		SAE 11		SAE 110	
	Bearing	Ingot	Bearing	Ingot	Bearing	Ingot
Sn, min.....	90.0	90.75	86.0	87.25	87.75	89.0
Sb.....	4.0–5.0	4.25–4.75	6.0–7.5	6.5–7.0	7.0–8.5	7.25–8.25
Cu, max.....	4.0–5.0	4.25–4.75	5.0–6.5	5.5–6.0	2.25–3.75	2.25–3.5

(a) Lead content limited to 0.35% max, but 0.60% Pb is permissible in finished bearings backed with steel or bronze, provided a lead-tin solder has been used in bonding the bearing material to the backing.
(b) Other elements (max): 0.08% Fe, 0.10% As, 0.08% Bi, no Zn or Al.

The presence of zinc in these bearing metals is not generally favored. According to Freeman and Brandt,[1] arsenic increases the resistance of these alloys to deformation at all temperatures, while zinc has a similar effect at 100 F, but causes little or no change at room temperature. Zinc has a marked effect on the microstructure of certain of these alloys.[3] Small quantities of aluminum, even less than 1%, will modify the microstructure of these alloys.

Bismuth is objectionable because, in combination with tin, it forms a eutectic that melts at 279 F, so at temperatures higher than this, the strength of the alloys is decreased appreciably.

In high-tin alloys (such as ASTM Grades 1, 2 and 3, and SAE 10, 11 and 110) lead is limited to 0.35%. This is because of the deleterious effect of lead on the strength of

Table III. Compositions and Physical Properties of Tin-Base Bearing Alloys

ASTM Alloy Grade	Specific Gravity	Composition, %				Compression Tests[a] Yield Point,[b] psi		Compression Tests[a] Ultimate Strength,[c] psi		Brinell Hardness[d]		Melting Point		Temp of Complete Liquefaction		Proper Pouring Temp

(a) The compression-test specimens were cylinders 1½ in. long and ½ in. in diam, machined from chill castings 2 in. long and ¾ in. in diam.
(b) Values for yield point were taken from stress-strain curves at a deformation of 0.125% reduction of gage length.
(c) Values for ultimate strength were taken as the unit load necessary to produce a deformation of 25% of the length of the specimen.
(d) Tests were made on the bottom face of parallel machined specimens cast at room temperature in a steel mold 2 in. in diam by ⅝ in. deep. Values listed are the average of three impressions on each alloy, using a 10-mm ball and applying a 500-kg load for 30 sec.

these alloys at temperatures of 302 F or more. Lead and tin form a eutectic that melts at 361 F. Bearings that exceed this temperature naturally become fragile as a result of the formation of a liquid phase within them.

The mechanical properties of ASTM Grades 1 to 5 have been investigated intensively by Freeman and Woodward.[5] The principal results of their work are shown in Table III.

Values for Brinell hardness number, limit of proportionality, yield strength in compression, and compressive strength (load per unit initial area required to compress test pieces 0.250 in. per in. of length) of representative Sn-Sb-Cu alloys are given in Table IV, taken from the work of Ellis and Karelitz.[6]

An important point brought out by Freeman and his collaborators is that the total deformation of the sample in the compression testing of babbitts is a function of the duration of application of the load—a point sometimes overlooked by those reporting and studying results of tests on materials as plastic as these alloys. What is true of the compression test is true also of other types of static tests. Still, the known limitations of static tests do not discount their value. A Brinell test, for example, wherein the load is applied for a standard time (for instance, 30 sec) is of considerable value for purposes of manufacturing control. Between the Brinell hardness numbers of the tin-base bearing materials and their properties in compression, the relationship is close enough to permit a fair estimate of the properties in compression to be made on the basis of Brinell tests alone. A knowledge of the properties of these alloys in compression, though useful, is not so important as an understanding of the beneficial effects on bearing life brought about by reducing the thickness of liners in bearings, particularly in those to be subjected to repeated stress. The type of relationship that exists between bearing life and thickness of babbitt is made clear in Fig. 1.[7]

Compared with other bearing materials, the tin-base alloys have relatively low resistance to fatigue, but their resistance is sufficient to warrant the use of these alloys in low-load situations. An important point is that these alloys are commercially easy to bond and to handle and have excellent antiseizure qualities. Further, they resist corrosion much better than lead-base bearing alloys.

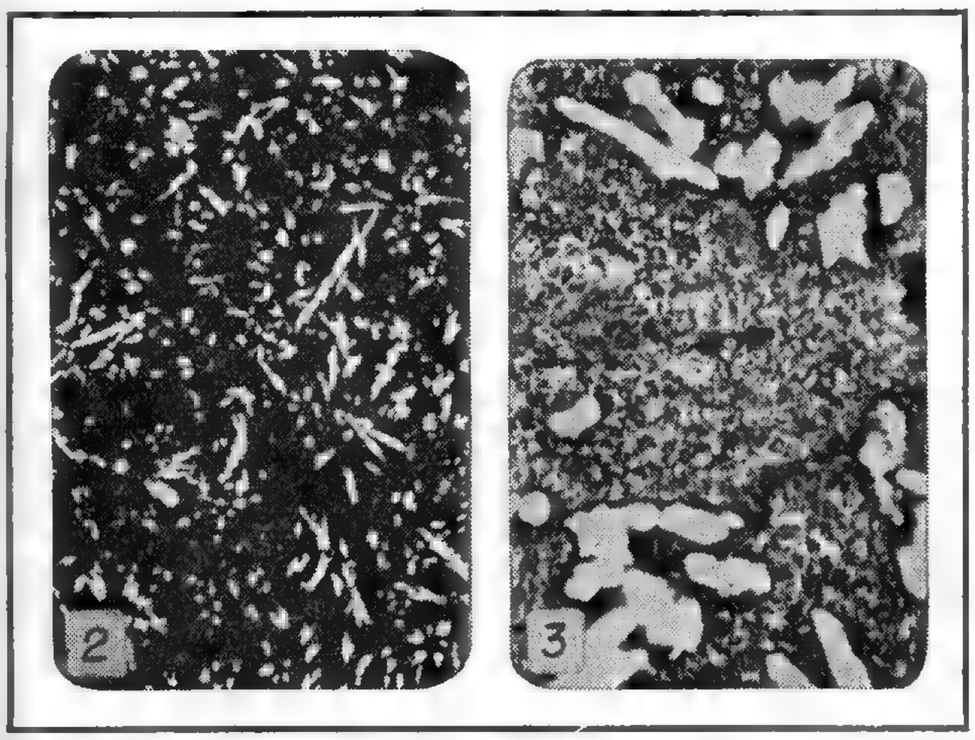

Fig. 2 Microstructure of tin-base bearing alloy containing 91% Sn, 4.5% Sb, 4.5% Cu (ASTM Grade 1, SAE 10) × 100. Etched with ferric chloride solution

Fig. 3 Same as Fig. 2 except × 500

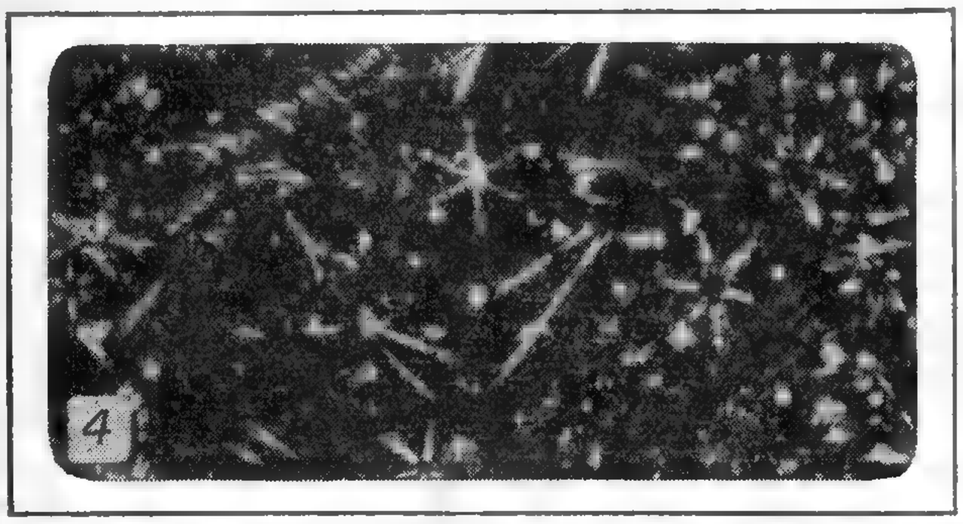

Fig. 4 Microstructure of strip-cast tin-base bearing alloy containing 89% Sn, 7.5% Sb, 3¼% Cu (ASTM Grade 2, SAE 110) × 500. Etched with ferric chloride solution

Structure consists of a tin-antimony solid solution matrix in which are embedded hexagonal dendrites and rodlike crystals of the eta (Sn-Cu) phase and very small round particles of the beta (Sb-Sn) phase, precipitated from solid solution.

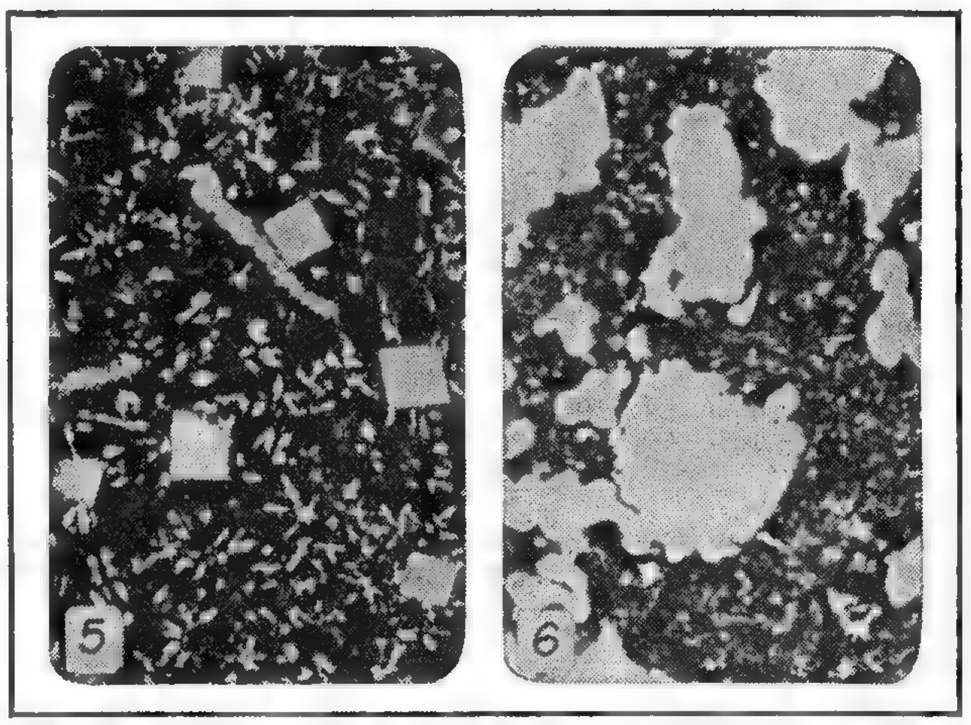

Fig. 5 Microstructure of tin-base bearing alloy containing 83.3% Sn, 8.3% Sb, 8.3% Cu (ASTM Grade 3) × 100. Etched with ferric chloride solution

Fig. 6 Same as Fig. 5 except × 500

Of the above alloys, ASTM Grade 2 (SAE 110) is most widely used in the automotive field at the present time. ASTM Grades 4 and 5 have a rather limited application and are relatively unimportant.

The structures of these alloys vary in accordance with their composition. Alloys that contain from about ½ to 8% Cu and less than about 8% Sb are characterized by a matrix (solid solution) in which needles of a copper-rich constituent and fine rounded particles of precipitated SbSn are distributed (Fig. 2 and 3). The proportion of the copper-rich constituent increases with copper content. ASTM Grade 2 (SAE 110) in the form of bearings has a structure of this type in which the needles often assume a characteristic hexagonal star-like pattern (Fig. 4). Alloys that contain from about ½ to 8% Cu and more than about 8% Sb exhibit primary cuboids of SbSn as well as needles of the copper-rich constituent in the matrix of solid solution (Fig.

Table IV. Effects of Antimony and Copper on Some Mechanical Properties of Sn-Sb-Cu Alloys at Room Temperature

Sb, %		Copper, percentage 0.5	1	2	4	8

5 and 6). In alloys that contain about 8% Sb and from about ½ to 8% Cu, rapid cooling has the effect of suppressing the formation of the cuboids of SnSb. This is particularly true of alloys containing the lower percentages of copper. (Study of the article on Cu–Sb–Sn in the CONSTITUTION OF ALLOYS Section of this Handbook, will assist in the interpretation of the above structures.)

Table V. Chemical Compositions of Lead-Base Bearing Alloys (ASTM B 23-46T)

(a) Other elements: zinc and aluminum not to exceed 0.005% when determined on a 10-g sample.

Alloy Grade 9 was discontinued in 1946

Lead-Base Alloys. The lead-base bearing alloys, also known commercially as "babbitt metals" or "babbitts", are of two types:

1 Alloys of lead, tin, antimony and, in many instances, arsenic.
2 Alloys of lead, calcium, tin and the alkaline earth metals.

Many alloys of the first type have been known for centuries in the form of type metal, and were probably employed as bearing materials because of some of the properties they were already known to possess. The advantages of arsenic additions in this type of lead-base bearing alloy have been generally recognized only during the last ten years. Alloys of the second type were developed in the early part of the present century.

Typical of the Pb-Sn-Sb-As alloys are the various grades of the ASTM Tentative Specifications for White Metal Bearing Alloys already referred to. The compositions of these alloys are listed in Table V.

The three SAE Specifications that cover lead-base bearing alloys are given in Table VI.

The properties of lead-base bearing materials[5] referred to in the ASTM specifications are quoted in Table VII.

In the absence of arsenic, the microstructure of these alloys consists of cuboid-shaped primary crystals of SbSn or of antimony embedded in a ternary mixture of Pb-Sb-SbSn in which lead forms the matrix. The amount of these cuboids per unit volume of alloy increases as the antimony content increases. If the antimony content is more than about 15% in these alloys, the total amount of the hard constituents increases to such an extent that the alloys become too brittle to be useful as bearing materials.

The main advantage of adding arsenic to these alloys consists in the improvement of their mechanical properties, particularly at elevated temperatures.[2] All lead-base babbitts are subject to softening or loss of strength during

Table VI. Chemical Compositions of Lead-Base Bearing Alloys (SAE)

Element	Composition, percentage[a] SAE 13 Bearing	SAE 13 Ingot	SAE 14 Bearing	SAE 14 Ingot	SAE 15 Ingot
Sn	4.5 – 5.5	4.75– 5.25	9.25–10.75	9.75–10.25	0.9 – 1.25

As	0.60 max	0.60 max	0.60 max	0.60 max	0.80– 1.10

(a) Other elements: zinc and aluminum not to exceed 0.005% in a 10-g sample.

prolonged exposure to the temperatures (200 to 300 F) at which they serve as bearings in internal-combustion engines. The addition of arsenic minimizes this softening. Under suitable casting conditions, the arsenical lead babbitts—for example, ASTM 15 (SAE 15)—develop remarkably fine and uniform structure (Fig. 7). They also have excellent fatigue strength. (*See* Table VIII; note, however, that results from rotating-beam fatigue tests cannot be translated directly into bearing-fatigue performance.)

The arsenical babbitts are giving satisfactory service in many applications. The use of these alloys increased greatly during World War II, particularly in the automobile industry and in Diesel engines. The alloy most widely used is ASTM Grade 15 (SAE 15), containing 1% As. The automobile passenger-car bearings of this alloy are usually made from continuously cast bimetallic (steel-babbitt)

(c) Test specimens chill cast to size and held at the testing temperature for 20 minutes before testing

strip. When properly handled, the alloy will withstand the considerable strain that results from forming the bimetallic strip into bearings. Diesel engine bearings are often cast as individual bearings, either by centrifugal casting or by gravity casting methods.[9] In applications where higher hardness is required and where the formability requirements are not so severe (for instance, in rolling-mill bearings) an alloy that contains 3% As has been used successfully. The bond between arsenical lead babbitts and copper alloy backs is often of poor quality.

Copper is said to be effective in preventing segregation, but, mainly because it is the apparent cause of frothing when alloys of low tin content are being poured, it is limited in these alloys to 0.5% max (*see* Tables V and VI).

For many years the lead-base bearing alloys were considered low-cost substitutes for the tin-base alloys. There is not much difference between the antiseizure characteristics of the two groups of alloys. During the last decade it has been found that when the lead-base alloys are used in reduced thicknesses (0.030 in. or less) the resistance to fatigue is at least equal to that of the tin-base alloys, if not better. Bearings of any of these alloys remain serviceable longest when made 0.005 in. thick or less. The superiority of the lead-base over the tin-base alloys becomes more marked as operating temperatures increase. This accounts for the fact that automotive engineers generally favor lead-base alloys of compositions that approximate SAE 14 and 15, referred to in Table VI, and ASTM Grade 15, referred to in Table V.

Table IX. Chemical Compositions of Cadmium-Base Bearing Alloys

Element	Composition, percentage SAE 18	SAE 180
Cadmium	98.4 min	98.25 min
Nickel	1.0 to 1.6	.....
Silver	0.01 max	0.5 to 1.0
Copper	0.20 max	0.4 to 0.75
Tin	0.02 max	0.01 max
Lead	0.05 max	0.02 max
Zinc	0.05 to 0.15	0.02 max

The resistance to fatigue of bearing materials depends, to a great extent, on the design of the bearing. The strength and rigidity of the supporting structure, the thickness of the backing metal (steel or bronze), the thickness of the bearing material, and the character of the bond between the bearing material and the backing, are all factors of consequence in bearings for use in high-speed reciprocating engines, such as the main and connecting-rod bearings of automobile and aircraft engines. Resistance to fatigue is of somewhat less importance in bearings that operate under more or less static load; for example, journal bearings in locomotive tenders and passenger and freight railway cars. These bearings are lined to a thickness of ¼ in. unless otherwise specified. (*See* ASTM Specifications for Car and Tender Journal Bearings, Lined—ASTM Designation: B 67-46). In such bearings as these, resistance to abrasion, antiseizure characteristics, deformability, compressive strength and resistance to corrosion are of greater significance than resistance to fatigue. The lining metal generally employed in car and tender journal bearings (ASTM B 67-46) conforms to the following requirements for chemical composition:

Tin, per cent	as specified
Antimony, minimum per cent	8.0
Tin and antimony, per cent	10 to 14
Arsenic, maximum per cent	0.2
Copper, maximum per cent	0.5
Sum of tin, antimony, lead, and arsenic, min per cent	99.25
Other impurities, maximum per cent	0.75

Pouring temperature and rate of cooling exert a profound influence on the microstructure and properties of lead-base alloys, particularly when they are used in the form of the relatively heavy liners employed in railway journals. High pouring temperatures and slow cooling rates, such as result from the use of overhot mandrels, promote segregation and the formation of a coarse structure. A coarse structure may cause brittleness, low compressive strength and low hardness. Low pouring temperatures (620 to 650 F) are therefore to be recommended. Since these alloys remain relatively fluid, almost to the point of complete solidification (about 465 F for most of these lead-base alloys) they are easy to manipulate and can be handled with no great loss of metal from drossing.

The use of the lead-base babbitts containing calcium and the alkaline earth metals, is confined almost entirely to the railway field although these babbitts are employed also in certain Diesel bearings.

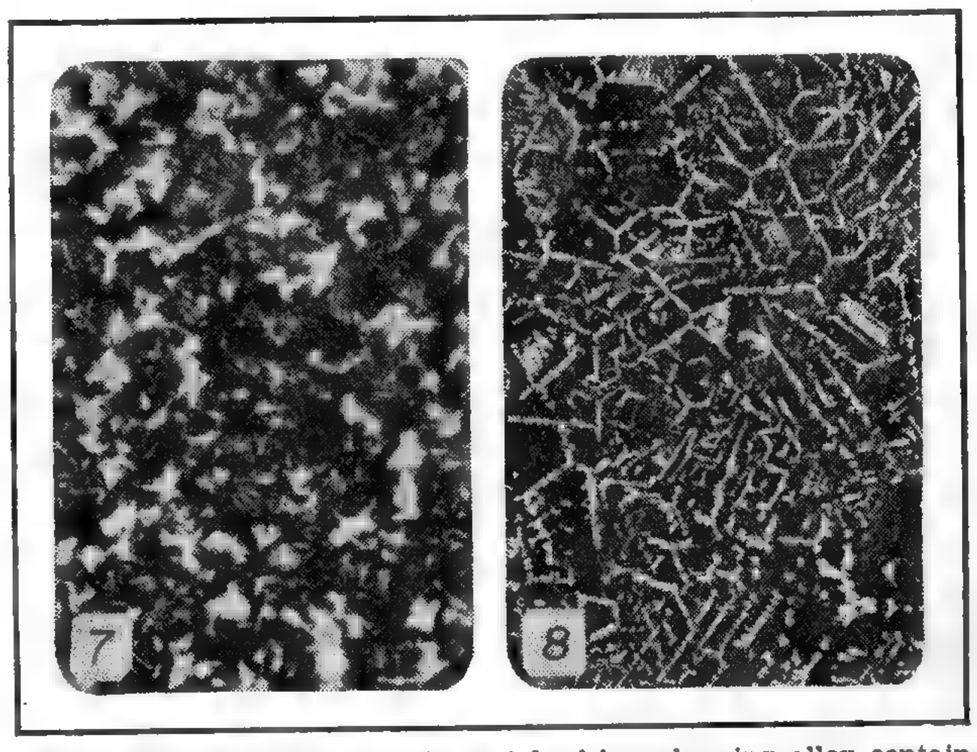

Fig. 7 Microstructure of strip-cast lead-base bearing alloy containing 82.5% Pb, 15% Sb, 1% Sn, 1% As (ASTM Grade 15; SAE 15) × 1000. Etched with ferric chloride solution

Structure consists of primary dendrites of lead and primary particles of antimony and of the beta (Sb-Sn) compound; matrix is a eutecticlike structure

Fig. 8 Microstructure of a die-cast cadmium-nickel bearing alloy containing 1¼% Ni (SAE 18) × 100. Etched with ferric chloride solution

Structure consists of large dendrites of $NiCd_7$ compound embedded in a matrix of nearly pure cadmium

One of the most widely used of these alloys contains 1.0 to 1.5% Sn, 0.50 to 0.75% Ca and small amounts of various other elements. The strength of this alloy approximates that of the alloy that contains 90% Sn, 8% Sb and 2% Cu, referred to in Table IV. The Brinell hardness number is about 20, and the solidus is 610 F. The liquidus is probably near 640 F. The pouring temperature varies from 930 to 970 F. This is relatively high and accounts for the formation of a larger volume of dross than is encountered when melting the lead-base Pb-Sb-Sn alloys. Care must be taken to avoid contamination of the alloy by antimonial lead-base babbitts, and vice versa. The resistance to wear and the deformability are of the same order as those of the other lead-base babbitts. Most compositions of this type of alloy are subject to corrosion by acidic oils.

Table X. Chemical Compositions of SAE 48 and SAE 480 Copper-Lead Bearing Alloys

Element	Composition, percentage SAE 48	SAE 480
Copper	67.0 to 74.0	60.0 to 70.0
Lead	25.0 to 32.0	30.0 to 40.0
Silver	1.5 max	.....
Zinc	0.1 max	.....
Phosphorus	0.025 max	.....
Iron	0.35 max	0.35 max
Tin	.....	0.05 max
Other elements	0.15 max	0.3 max

Cadmium-Base Alloys. In all likelihood the limited availability of cadium has been the main reason why cadmium alloys have not been more widely employed in the manufacture of bearings. Within the last 12 years, cadmium alloys hardened by nickel (SAE 18) or by silver and copper (SAE 180) have come to the fore because of having greater resistance to fatigue than the babbitts. Compositions are listed in Table IX.

These alloys are readily corroded by some oils; however, attack can be retarded by the diffusion of indium into the

bearing surfaces from an electrodeposited layer of the metal.

The main advantage of SAE 18 over SAE 180 is that it bonds readily with steel. Because of the nickel in the alloy, the bond is strong and ductile. The structure of a die-cast cadmium-nickel bearing alloy (SAE 18) is shown in Fig. 8.

Copper-Lead Alloys. Copper-lead alloys are used extensively both in the automotive and aircraft fields and in the field of general engineering.

In the aircraft and automotive fields these alloys are used almost exclusively in steel-backed bearings, a majority of which (for the automotive field) are blanked from steel strip continuously coated with alloy in automatically controlled machines. This same general method of manufacture is used in the production of most steel-backed babbitt bearings. Typical alloys are SAE 48 and SAE 480, of which the compositions are listed in Table X.

SAE 48 was designed originally for aircraft engine bearings. It is now being adopted by automotive engineers. Figure 9 shows the structure of SAE 48 in the form of a gravity-cast bearing. SAE 480 is used exclusively in general automotive practice. The tolerance for lead in SAE 480 is purposely made broad enough to cover the several compositions now in commercial use. Closer tolerances can be specified by the purchaser of these alloys.

Copper-lead alloys that contain about 30% Pb and as much as 5% Ag, have been used in the automotive industry. Another type of bearing has an intermediate layer of 25% Pb copper-lead cast on a steel back and a thin plated overlay of lead-tin alloy. Figure 10 shows the structure of the copper-lead layer in a bearing of this type. Although the field experience with these three-layer bearings is as yet limited, they have already proved their exceptionally high resistance to fatigue.

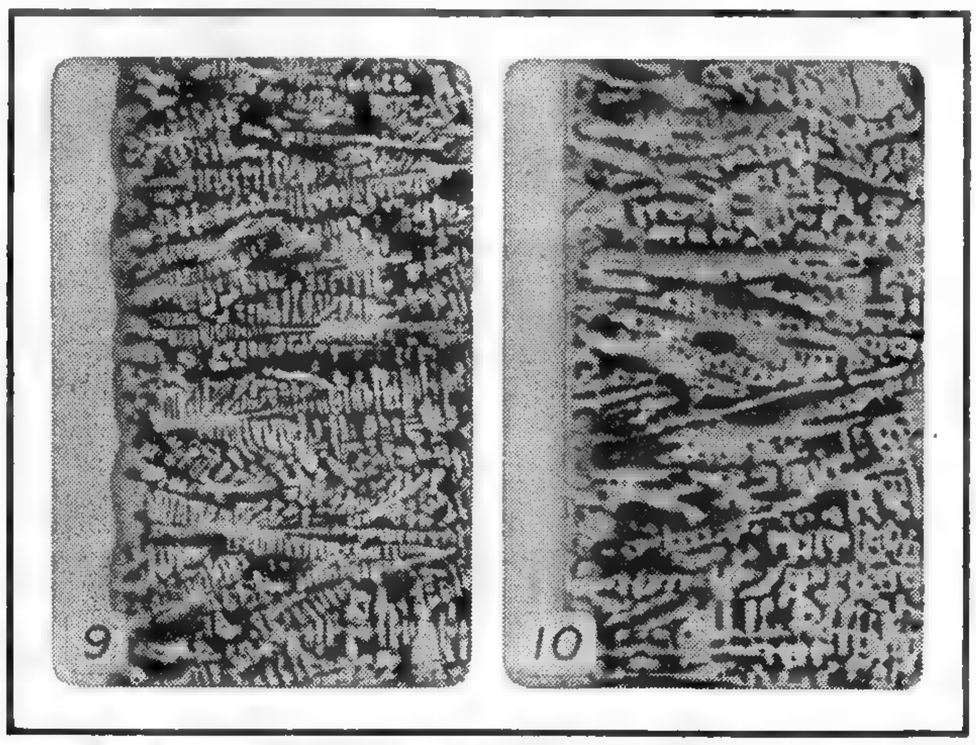

Fig. 9 Microstructure of a gravity-cast copper-lead bearing containing 28.5% Pb, 1¼% Ag, remainder copper (SAE 48) × 100

Bond between copper-lead alloy and steel is shown. The structure consists of copper dendrites that are approximately perpendicular to the bond surface. The space between the dendrites is filled with lead.

Fig. 10 Microstructure of a strip-cast copper-lead bearing containing 25% Pb, 0.25% Sn, remainder copper, × 100

This alloy is used as the intermediate layer in a three-layer bearing construction. Micrograph shows the bond between copper-lead alloy and steel. The structure consists of copper dendrites that are approximately perpendicular to the bond surface. The space between the dendrites is filled with lead.

The higher the lead content of the copper-lead alloys, the lower is the fatigue strength and the higher the antifrictional characteristics. Silver and tin may be substituted for part of the copper in order to increase fatigue strength. To prevent seizing, a thin coating of lead alloy is sometimes plated over these bearing materials. This lead, of course, wears away in time. Like the cadmium-base alloys, these alloys are easily corroded by certain oils. In fact, corrosion is a major problem with copper-lead alloys. For protection, indium can be diffused into the bearings by suitable heat treatment after the bearings are electroplated with indium.

Copper-lead bearings are also made by applying copper-lead powder to steel strip that is passed continuously through furnaces where the mixtures are simultaneously sintered and bonded to the strip. In these bearings the somewhat elongated and recrystallized copper grains tend to lie parallel to the surface of the strip, whereas in cast copper-lead strip bearings, the copper dendrites are essentially perpendicular to the surface of the strip.

Table XI. Approximate Mechanical Properties of Sand-Cast Copper-Lead Bearings Containing 30 and 40% Pb

Property	30% Pb	40% Pb
Tensile strength, psi	8000 to 9000	7500 to 8500
Elongation, % in 2 in.	6 to 8	6 to 8
Compressive strength,(a) psi	3000	2500
Brinell hardness number	22.5 to 32.5	20 to 30

(a) 0.001 in. compression on sample 1 in. high and 1 in. in diam

In the field of general engineering, alloys of copper and lead have found application as bearings, but a wider application as bushings. The hardness and the compressive and tensile strengths of these alloys decrease as the lead content is increased. Table XI presents *very approximate* limits for the mechanical properties of sand-cast bearings of these materials.

The properties of these alloys are profoundly affected by the method of manufacture and by the size of the casting section. They have good antiseizure characteristics and can be used with some success in situations where lubrication is uncertain or intermittent. Although copper-lead bearings are used without special support in some installations, it is general practice in the automobile field to apply these alloys as a thin layer on a steel shell.

Table XII. Chemical Compositions of Tin Bronze Castings (ASTM B 22-46T)

Element	Composition, percentage — Class A	Class B	Class D
Copper	79 to 82	82 to 85	86 to 89
Tin	18 to 20	15 to 17	▮ to 11
Zinc	0.25 max	0.25 max	1.0 to 3.0
Lead	0.25 max	0.25 max	0.30 max
Nickel	.....	.....	1.0 max
Iron	0.25 max	0.25 max	0.15 max
Phosphorus	1.0 max	1.0 max	0.05 max

In slowly cooled castings, such as sand castings, lead may segregate, so tin, nickel, manganese and other elements are added to reduce this segregation. These elements increase the strength of the basic alloy and provide materials that are used considerably in engineering.

Tin Bronzes and Leaded Tin Bronzes. *Tin Bronzes.* The bearing bronzes are substantially alloys of copper with from 5 to 20% Sn and a small percentage of residual phosphorus, that is, phosphorus remaining after deoxidation of the alloys with 10 or 15% phosphor copper. These alloys are sometimes referred to as "phosphor bronzes".

Table XIII. Required Mechanical Properties of Tin Bronze Castings (ASTM B 22-46T)

Property	Alloy — Class A	Class B	Class D(a)
Deformation limit,(b) psi	24,000 min	18,000 min	.....
Permanent set,(c) in. per in.	0.04 to 0.12	0.10 to 0.20	.....

(a) Tensile strength, 36,000 psi min; elongation in 2 in., 18% min
(b) Load that produces a permanent set of 0.001 in. in a cylindrical test specimen 1 sq in. in cross-sectional area and 1 in. high
(c) Under a load of 100,000 psi

When zinc is used instead of phosphorus, ▮ to 6% Zn may be used in the bronze, which is then quite generally referred to as "gun metal" (Government bronze, composition G, Admiralty bronze or zinc bronze).

Phosphor bronzes are chosen where load-carrying capacity at low speeds is of paramount importance, while gun metal is preferred where complicated castings are specified and where difficulties may be encountered in the foundry.

Typical of the phosphor bronzes are two of the alloys covered by the ASTM Tentative Specifications for Turntables and Movable Bridges (B 22-46T). The compositions and specified mechanical properties of tin bronzes, are shown in Tables XII and XIII.

These cast tin bronzes are ordinarily used for the following purposes:

Class A. For contact with hardened steel disks at low speeds under pressures not greater than 3000 psi, as in the disk bearings of center-bearing swing bridges.

Class B. For contact with hardened steel disks at low speeds under pressures not greater than 2500 psi, as in the disk bearings of turntable and center-bearing swing bridges; for contact with steel that has a tensile strength of not less than 60,000 psi, at low speeds under pressures not greater than 1500 psi, as in trunnions and movable bridges; and for bearing and expansion plates under pressures not exceeding 2500 psi.

Other alloys of this type are covered by the ASTM Tentative Specifications for Tin Bronzes and Leaded Tin Bronze Sand Castings (B 143-46T). The chemical and tensile requirements for these alloys are quoted in Tables XIV and XV.

Table XIV. Chemical Compositions of Tin Bronze and Leaded Tin Bronze Sand Castings (ASTM B 143-46T)

	Composition, percentage							
	Tin Bronze				Leaded Tin Bronze			
	1A[a]		1B[a]		2A[a]		2B[a]	
Element	Min	Max	Min	Max	Min	Max	Min	Max
Copper	86.0	89.0	86.0	89.0	86.0	90.0	85.0	89.0
Tin	9.0	11.0	7.5	9.0	5.5	6.5	7.5	9.0
Lead	...	0.30	...	0.30	1.0	2.0	...	1.0
Zinc	1.0	3.0	3.0	5.0	3.0	5.0	3.0	5.0
Nickel	...	1.0	...	1.0	...	1.0	...	1.0
Iron	...	0.15	...	0.15	...	0.25	...	0.25
Phosphorus	...	0.05	...	0.05	...	0.05	...	0.05

(a) The chemical requirements of SAE Specifications 62, 620, 621 and 622 conform to those for alloys 1A, 1B, 2B and 2A, respectively.

These specifications also cover two leaded tin bronzes, to which reference will be made below. Alloys 1A and 1B (Table XIV) are frequently referred to as 88-10-2 and 88-8-4 respectively. They are important both because of their good casting characteristics and because of their strength, toughness, bearing qualities and, in particular, their resistance to corrosion in sea water.

Phosphorus and zinc together in the same alloy confer no useful properties that cannot be obtained by one element or the other alone. However, phosphorus is commonly employed as a deoxidizer in making gun metal. On the other hand, zinc is rarely, if ever, added intentionally to phosphor bronze. Phosphorus must be used with discretion in making gun metal because it has a great effect on the freezing range of the alloy. As might be expected, variations in the freezing range affect the casting characteristics of the material. Sound sand castings can never be produced consistently unless uniform conditions are maintained in the foundry. In summary it may be said that gun metal should contain preferably no more than a trace of phosphorus, and phosphor bronze should contain no zinc.

Table XV. Required Tensile Properties of Tin Bronze and Leaded Tin Bronze Sand Castings (ASTM B 143-46T)

	Tin Bronze		Leaded Tin-Bronze	
Property	1A	1B	2A	2B
Tensile Strength, min, psi	40,000	40,000	34,000	36,000
Yield Strength,[a] min, psi	18,000	18,000	16,000	16,000
Elongation in 2 in. min, per cent	20	20	22	18

(a) Yield strength determined as the stress producing an elongation under load of 0.5%, that is, 0.01 in. in a gage length of 2 in.

In general the substitution of zinc for tin in bronze results in an improvement in ductility and the sacrifice of a measure of strength and hardness. In instances where strength and hardness are essential it may be desirable to limit the use of zinc, but when zinc is allowed by specification, the engineer can be sure almost invariably of a consistent output of sound, clean castings.

Lead usually, though not always, decreases the hardness and strength of gun metal. However, machinability is improved by the addition of a small amount of lead; ½% Pb will render gun metal free-cutting. It is better practice to keep the lead content below ½% in foundry production, because of the danger of exceeding this amount as a result of the pyramiding of lead from scrap returns. It will be noted that, in the above specifications for castings of tin bronze, the lead content is limited to either 0.25 or 0.30% max.

Iron increases the hardness of gun metal and is objectionable because of its tendency to produce hard spots that may seriously reduce machinability.

Nickel is beneficial rather than detrimental to the casting properties of the tin bronzes. It does not affect adversely their resistance to abrasion or corrosion, and tends to reduce grain size. Generally it is not added to 88-10-2, but is commonly present in 88-8-4 to the extent of from 0.50 to 0.75%.

Table XVI. Chemical Compositions of Leaded Tin Bronzes (SAE)

	Composition, percentage			
Element	SAE 791, Rolled or Wrought	SAE 792, Cast Lining	SAE 793	SAE 794
Copper	remainder	remainder	83.0 min	68.5 to 75.5
Tin	3.5 to 4.5	9.0 to 11.0	3.5 to 4.5	3.0 to 4.0
Lead	3.5 to 4.5	9.0 to 11.0	7.0 to 9.0	21.0 to 25.0
Zinc	1.5 to 4.0	0.5 max	4.0 max	3.0 max
Antimony	.....	0.5 max	.....	.....
Nickel	.....	0.5 max	.....	.....
Iron	0.1 max	0.35 max	0.35 max	0.35 max
Other elements	0.2 max	0.4 max	0.3 max	0.4 max

SAE 791 to 794 may be indented and graphited.

SAE 792, 793 and 794 are the cast, or cast and rolled, bronze liners for a rolled split bushing made with a steel backing, usually SAE steel 1010 or 1015. These materials may be rolled and annealed to any desired specification for hardness. When rolled, antimony is 0.25% max to prevent rolling difficulties.

SAE 793 and 794 are liners for steel-backed, split bearings similar in construction to SAE 792.

Leaded Tin Bronzes. The wrist-pin alloys and miscellaneous bushing alloys covered by SAE Specifications 791 to 794 (Table XVI), are typical of low-leaded tin bronzes. Other compositions are those mentioned in Table XIV and the alloy referred to as "Class C bronze" in ASTM Specification B 22-46T, which also covers Classes A, B and D in Table XII. Composition of Class C bronze is essentially the same as that of SAE 792, given in Table XVI.

Class C bronze, as well as other leaded tin bronzes, is used for ordinary bushings in machinery, but is employed specifically in bearing and expansion plates under pressures not greater than 1000 psi. Eash[11] found that a copper alloy containing 8% Ni, 10% Pb, 2% Sn and 1% Sb, appeared to be a promising substitute for Class C bronze when used in the sand-cast condition.

Table XVII. Chemical Compositions of Aluminum-Base Bearing Alloys

	Composition, percentage				
Element	750[13]	XA750[14]	XB750[15]	XB80S	Al-Cd-Si[16]
Tin	6.5	6.5	6.5	6.5	...
Copper	1.0	1.0	2.0	1.0	...
Nickel	1.0	0.5	1.2	0.5	...
Silicon	...	2.5	...	1.5	4.0
Magnesium	...	...	0.8	...	...
Cadmium	...	...	...	...	1.2

Probably the most complete account of the mechanical and wearing properties of the leaded tin bronzes is that contained in two papers published by French and collaborators.[10] These workers observed: "There is a considerable range of chemical composition within which the variations in mechanical and wearing properties [of these alloys] are small. This includes a range of from 15 to 25% Pb and from around 4 to 7% Sn. Since alloys within the entire range have given reasonably good performance in locomotive and journal bearings, there does not seem to be justification for the wide variations in specifications now used by different carriers for parts subjected to similar service." Since these remarks were published (1928), some progress

has been made towards attaining uniformity of composition in the leaded tin bronzes.

Other important observations by these workers were:

1 Leaded tin bronzes that contain less than about 4% Sn are unsuited for general bearing service, since they have low resistance to deformation and wear rapidly in the absence of lubrication. However, some of the alloys—for example, those high in lead—can serve satisfactorily for special service that involves low loads.

2 Bronze with from 8 to 10% Sn and 12 to 15% Pb seems better adapted than bronze with around 4 to 6% Sn, for service where the chief requirements are resistance to pounding and static stress.

3 In alloys with a nearly constant ratio of copper to tin, an increase in the lead content produces a general improvement in wearing properties, but this is more marked between 0.25 and 12% Pb than between 12 and 25% Pb. Concurrently, resistance to pounding, notch toughness and tensile strength decrease.

4 In alloys with a nearly constant ratio of copper to lead, increase in tin from 0.7 to about 5% results in a marked decrease in the wear produced by rolling and sliding friction without oil, and a general improvement in the wearing properties. Further increase in tin from about 5 to 10% does not greatly modify the wearing properties but does result in improved tensile strength and resistance to pounding. An improvement in notch toughness results when tin is increased to about 7%, which represents the proportion of this element above which appreciable amounts of brittle alpha-delta eutectoid appear in the structure of these alloys. With high tin, a slight decrease in notch toughness occurs.

5 As a general rule, chill-cast bronzes wear faster and have lower notch toughness than corresponding sand-cast bronzes. However, the chill-cast alloy has better resistance to pounding and higher tensile strength at all temperatures between 70 and 600 F. There are a few exceptions to this rule, for details of which reference should be made to the papers mentioned above.[10]

6 The addition of 4% Zn to these bronzes has, in general, a small effect on the properties referred to above. The work of French and his collaborators seems to justify the conclusion that the effects of zinc up to 4% are ordinarily small and may be insignificant in comparison with changes in properties occasioned by variations in foundry practice.

Silver. Electroplated bearings of three-layer construction[12] have been adopted in the aircraft industry. These bearings consist of steel shells electroplated with silver, which are then machined to very close dimensional tolerances and finally precision-plated to size, first with lead and then with indium or tin. This type of bearing has greater fatigue strength and higher load-carrying capacity than any other type used in aircraft at present (1947). Optimum fatigue strength and highest antiseizure properties are obtained only by using silver of the highest purity. Before use, the bearings are annealed so that the indium or the tin will diffuse into the lead. This annealing should be controlled carefully, so as to obtain the best results from the bearings in service.

Aluminum-Base Alloys. Since 1937 several aluminum alloys have been developed with mechanical and physical characteristics specifically adapted to meet the requirements of bearing applications. One of these materials, alloy 750,[13] has advanced to a commercial status and is being used to an increasing extent, particularly in heavy-duty engines. Alloy XA750[14] has been employed in a number of experimental applications, with promising results. Alloy XB750[15] is preferred for applications requiring higher strength. An Al-Cd-Si alloy[16] has performed favorably in a number of tests.

Aluminum bearings have been used chiefly in the form of homogeneous, single metal parts, which are preferably of relatively heavy section and are usually produced as permanent mold castings. The cast material may be used

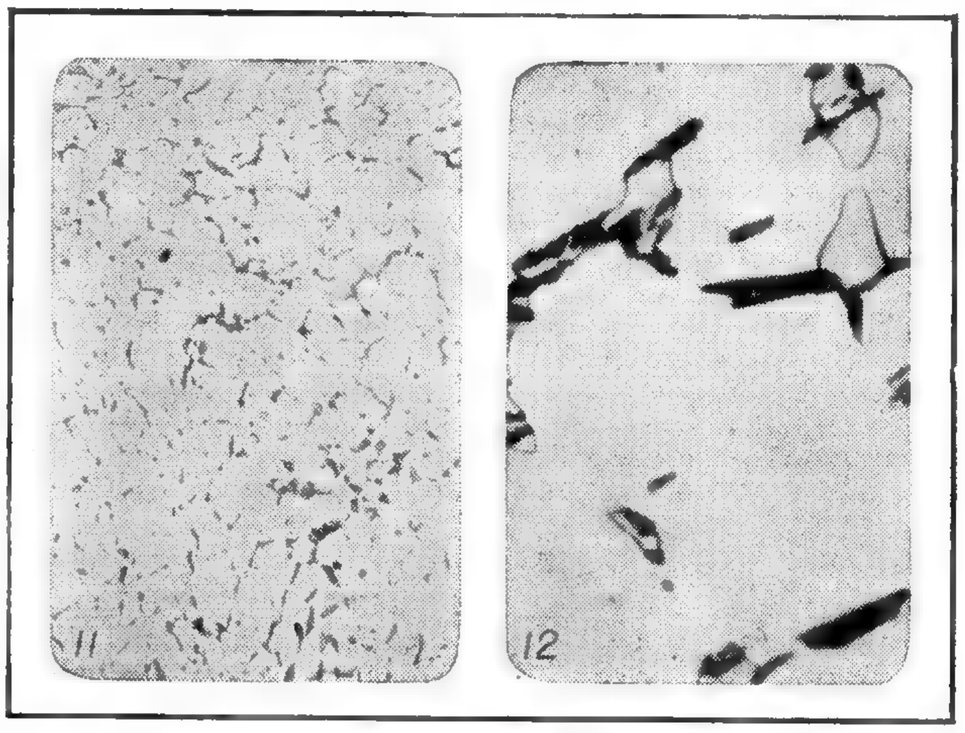

Fig. 11 Microstructure of permanent mold cast aluminum-base alloy 750–T5 in the heat treated condition, × 75

Fig. 12 Same as Fig. 11 except × 750. Outlined light particles, tin; acicular dark phase, $NiAl_3$; matrix, aluminum solid solution

in the heat treated condition or may be strengthened by cold working treatments. Recently alloy XB80S has been made available in the form of sheet, the mechanical properties of which are controlled by the final cold reduction. The Al-Cd-Si alloy also can be produced as sheet. When

Table XIX. Bearing-Fatigue Resistance and Antiseizure Properties of Various Bearing Materials Used in Alternating Load Applications

Except for the aluminum alloys, the materials are evaluated as steel-backed bearings under similar conditions. Aluminum alloys are evaluated as relatively thick, cast bearings.

Antiseizure Properties	Bearing-Fatigue Resistance: *Low*	*Low-Medium*	*High-Medium*	*High*
Very Poor				Tin bronzes Aluminum bronzes without lead
Poor				Silver 80–10–10 leaded bronze 88–4–4–4 leaded bronze 25% leaded bronzes
Medium		35% Pb copper-lead	28% Pb copper-lead with silver 25% Pb copper-lead with less than about 1% Sn	Aluminum-base alloys: 750 (cast) XB80S (rolled)
Good	Lead-base babbitts Tin-base babbitts	Cadmium-base alloys		

these aluminum alloys are used in ferrous housings, difficulties may result from differences between the coefficients of expansion of the two metals. Processes have been developed recently for bonding the aluminum bearing alloys to steel backing strip for thin automotive bearings.

The nominal compositions of the aluminum bearing alloys are listed in Table XVII.

The alloys have heterogeneous structures composed of a soft, low-melting constituent (tin or cadmium) and one or more relatively hard phases distributed throughout the aluminum solid solution matrix of moderate hardness (Fig. 11 and 12). These materials are characterized by high load-carrying capacity, high resistance to fatigue and excellent resistance to the type of corrosion encountered in bearing applications. However, the antiseizure properties are medium and the characteristics of embeddability are low, causing increased troubles at high surface speeds. Such troubles are experienced also with other hard bearing materials at high surface speeds.

Typical mechanical and physical properties of the aluminum-base bearing alloys are summarized in Table XVIII.

Fatigue Resistance, Antiseizure and Other Properties of Various Bearing Materials Used in Alternating Load Applications. Table XIX presents a classification that is necessarily crude. The antiseizure properties are very difficult, if not impossible, to measure in the laboratory. The ratings given are based on accumulated experience with materials that were in actual use as bearings. The resistance to fatigue can be measured quite accurately, but the fine differences are not considered here. It can be seen from the table that the stronger materials generally have poorer antiseizure characteristics. It is to be noted that the different materials, except the aluminum alloys, are evaluated as steel-backed bearings under similar conditions, for example, with the same thickness of layer. Solid aluminum bearings should be as thick as possible to provide the best performance. Table XIX refers to the results of tests on relatively thick aluminum alloy bearings.

Industrial Poisoning by Metals

By Marshall Clinton, Jr., M.D.* and Philip Drinker*

POISONING by metals, though less common than other hazards to health in industry, is frequent enough and severe enough to have made the toxicology of metals important in some of the industries that produce and fabricate metals. The poisoning discussed in this article is chiefly that resulting from inhalation or ingestion of metal fumes and dusts. Dangers from radioactive metals are not mentioned here. Some of the other hazards incidental to the processes used in refining and working metals, are mentioned; however most of the pertinent information on such hazards is included in the articles that deal with technical processes in this Handbook.*

Toxicity of the nonferrous metals is discussed below in the alphabetic order of the metals. A summary in tabular form is presented on page 759.

Aluminum. Aluminum is a metal of very low toxicity. Small amounts have been ingested daily by a sizable section of the American public ever since the introduction of aluminum cooking utensils. Aluminum is now commonly cast, machined and welded with no trouble or special risk except that of fire.

Water-soluble fluoride salts are being used to some extent in the molding sand for aluminum castings. When hot aluminum is poured into the sand, it causes the evolution of a certain amount of fluoride salts and some free hydrofluoric acid, which can cause fluorosis. Similarly, there is a definite fluoride exposure during shakeouts, especially if the sand and casting are hot.

The risk of developing silicosis while cleaning castings is about the same as in iron foundries (*see the article* "Blast Cleaning of Metals"). During World War II, many tons of both magnesium and aluminum were cast, apparently without bad results. However, it is early to give the process a clean bill of health, and until it has been proved safe, special attention should be directed toward the ventilation of the working areas in both aluminum and magnesium foundries. (*See* Magnesium, page 757.)

Beryllium.[1,2,3] Numerous reports of poisoning by the fumes and dusts that accompany the concentration and purification of beryllium can be found in medical journals. Two types of lung disease are recognized as results of exposure to beryllium. The first of these, encountered among workers exposed to moderately high concentrations of beryllium dusts, consists in an acute inflammation of the lungs, which terminates in a few weeks in complete recovery or death. The second type of lung disease caused by beryllium is encountered among workers exposed to low concentrations of beryllium for long periods, and consists in a delayed, chronic inflammation of the lungs that clinically resembles the disease known as sarcoid. This condition may not be noticeable until many months after exposure is terminated, and may persist for months or years, ending in recovery or death from intercurrent infection. Intermediate types of lung involvement may be encountered.

The mechanism by which beryllium produces lung disease and the degree and type of exposure required are not understood as yet. Prevention of poisoning depends on control of exposure to the dusts and fumes encountered in industries using beryllium. Recent reports indicate that beryllium in any form is toxic, even in extremely low concentrations, and that extreme precautions are necessary in its handling. No safe working limits can be given at present.

Cadmium.[4-9] Most reported instances of industrial cadmium poisoning have followed the breathing of freshly formed cadmium oxide fume generated by the overheating and oxidizing of cadmium. This happens most frequently when cadmium-plated steel is mistaken for galvanized iron

* Department of Industrial Hygiene, School of Public Health, Harvard University, Boston

* *See, for example,* "Blast Cleaning", "Cyaniding", "Metal Spraying", "Radiography", "Welding", "Powder Metallurgy".

and is welded without any special precautions. This type of poisoning may result also from any other process that greatly overheats cadmium and permits the resulting cadmium vapor to burn. Cadmium boils at 778 C but oxidation begins at considerably lower temperatures, which accounts for the characteristic olive-drab streaks around vessels in which cadmium has been heated carelessly.

The ingestion of cadmium in food or drink can also result in poisoning, but such instances are usually non-industrial in origin. They may follow the taking of acid foods and beverages prepared in cadmium-lined containers. An overdose of cadmium by mouth produces a severe gastrointestinal upset with nausea, vomiting, diarrhea and abdominal cramps.

Cadmium compounds may be handled with relative impunity, provided they are not heated sufficiently to produce cadmium oxide fumes. Inhaled cadmium oxide fumes have a delayed but devastating effect. During the first several hours of exposure there may be no discomfort, or the worker may notice mild irritation of the eyes, dryness in the throat and a feeling of tightness in the chest. These symptoms are generally not sufficient to drive him from the contaminated atmosphere; consequently exposure is continued. About four to eight hours after exposure has begun, the toxic effects of the metal become severe and coughing, soreness in the chest and difficulty in breathing are noted. These disorders may progress to severe pain in the chest; bluish discoloration of skin and lips because of insufficient oxygenation of the blood; and in the lungs a collection of blood-tinged fluid that is coughed up and expectorated. Abdominal pain, nausea and vomiting may follow. Death occurs in a considerable proportion of cases, yet those workers who do recover are generally entirely well in a few weeks.

Cadmium poisoning should be suspected if any worker develops evidence of severe lung irritation several hours after exposure to fumes produced during the overheating or welding of plated metals. Inquiry should be made concerning the breathing of any brown or yellow fumes before the onset of symptoms. If possible, air should be analyzed for cadmium under conditions simulating the exposure. If a piece of work is suspected, the parts should be examined to determine whether they are cadmium-plated.

The treatment of acute cadmium intoxication is a serious emergency. The slightest delay can be disastrous. The affected worker should be removed from the contaminated atmosphere and placed at *complete* rest, no matter how mild his symptoms, because the effects of the poison are delayed. The slightest exertion may aggravate the condition seriously. Oxygen and sedatives should be administered if necessary. In general, further treatment should be similar to the measures employed for severe gassing by substances such as chlorine or phosgene.

Adequate ventilation should be provided whenever cadmium-coated metal is welded or overheated. The recommended maximum allowable concentration of 0.1 mg of Cd per cubic meter of air seems desirable when cadmium oxide fumes are encountered; but this limit is probably needlessly low if applied to cadmium in dusts resulting from the handling of unheated cadmium compounds. Respirators may be effective in preventing serious exposure when the fumes cannot be controlled by ventilation, but the use of respirators is not advocated. If adequate ventilation cannot be supplied, then the operation should be discontinued or modified. Certainly the use of cadmium-plated containers for the preparation or storage of food or drink should be prohibited.

Chronic poisoning after prolonged exposure to cadmium hydroxide, has been reported in French publications, but seems unknown in this country. It is said to be characterized by a prolonged latent period, during which yellow discoloration of the tooth enamel is the only evidence of intoxication, followed in four to eight years by weakness and lancinating pain localized in precise bony areas that give evidence of specific bone changes when X-rayed.

Chromium.[10–13] Metallic chromium and its trivalent salts are nontoxic under all ordinary circumstances, but chromium trioxide or chromic acid and the various chromates and dichromates are systemic poisons as well as powerful local irritants.

Industrial chromium poisoning follows contact with one or more of these hexavalent chromium compounds through exposure to an atmosphere that contains the material in the form of vapor, mist, spray or dust; through direct contact with solutions that contain the material; or through handling the dry substance in the form of crystals or fine powder. Exposure is most prevalent in the electroplating industry but is also encountered in a considerable number of trades involving exposure to chrome.

Industrial chrome poisoning is characterized by lesions of the skin or mucous membranes. The most common skin lesion is the chrome ulcer or "chrome hole", which may be single or multiple. It is a slowly developing, indolent, painless ulceration of the skin and underlying tissues, with indurated and undermined edges that produce a characteristic "punched out" appearance. Penetration is deep and healing is slow, generally leading to extensive and distinctive scarring. Exposure may also produce a more diffuse raised or blistered rash over the fingers, hands, arms, and face, and occasionally on the feet and chest. Finally, the mucous membranes of the nose and throat may be severely irritated or ulcerated. This frequently leads to perforation of the nasal septum. Such perforations may develop after only one week of exposure and they are permanent. Systemic chrome intoxication may occur, characterized by gastrointestinal and kidney involvement, asthma and muscular twitching, but such intoxication is too rare to be important industrially.

Chrome poisoning can best be prevented by avoiding exposure. All operations involving the production of chromate or dichromate dust or mist should be sufficiently well ventilated to ensure a concentration of not more than 1 mg of chromic acid anhydride in 10 cu m of air. Plating tanks should be ventilated by exhaust slots along each side, rather than by an overhead hood. Operations that involve the handling or grinding of dusts should be mechanized as much as possible, and local exhaust ventilation should be used extensively.

Chrome workers should be trained to practice careful personal cleanliness, and adequate sanitary facilities must be provided. Each man should wash, and change his clothing when leaving work. All cuts and scratches should be treated immediately and protected by waterproof plaster or protective ointments. Frequent medical inspection of the skin is desirable. Protective clothing should be supplied wherever possible, and care must be taken to prevent chromate solutions from entering boots or gloves and remaining in intimate contact with the skin for long periods. Protective ointments may also be useful in preventing chrome lesions.

Copper. Copper is unimportant as an industrial health hazard. Copper oxide fumes may induce metal fume fever, but such fumes are rarely encountered, since the vapor pressure of copper is low (for example, less than 0.0001 atm at a temperature 300 C above the melting point). Copper sulfate in powder or liquid form may irritate the skin, producing a troublesome chronic eruption. Chronic poisoning by copper has been reported as a cause of hemochromatosis, or bronzed diabetes; but at present almost all authorities agree that systemic copper poisoning occurs rarely if ever and that its etiological role in hemochromatosis is in doubt.

Lead.[14–23] All forms of lead are potentially toxic, but poisoning most commonly occurs after the inhalation of lead fumes and very fine lead dusts. The risk of serious lead poisoning increases with reduction in particle size and increase in the rate of solution. Thus, the mining and concentration of galena (lead sulfide) gives no trouble at present, but the careless smelting and roasting of the concentrates can easily cause lead poisoning. A skilled welder of lead does not burn or volatilize the metal, because he controls the flame temperature carefully, but the novice may use too hot a flame and get lead poisoning.

The entrance of lead into the body does not mean that lead poisoning has occurred or will occur. Practical experience and systematic investigation have demonstrated that certain levels of occupational lead exposure and absorption are compatible with normal healthy existence and activity. Furthermore, the finding or existence of excessive

lead absorption and excretion in an individual who feels reasonably well and continues his work, does not constitute lead poisoning. Even poor appetite, constipation, a lead line and stippling are not considered symptoms. Lead poisoning should not be diagnosed unless the effects of lead absorption are sufficient to cause the individual to lose his sense of well-being and to complain of being ill.

Lead may enter the body by inhalation or ingestion. Either route may end in lead poisoning, but inhaled lead is decidedly more toxic than swallowed lead. All body tissues are exposed to lead after its absorption. The blood, muscles, kidneys and nervous system may be seriously injured by exposure to lead while the bones, liver and intestinal tract remain relatively unaffected by its presence. Lead enters the circulation at a variable rate, depending on the degree, type and severity of exposure. It is removed from the circulation by the intestines, which excrete it in the feces; by the kidneys, which excrete it in the urine; and by the skeletal system, which stores it in considerable amount in the mineral structure of the bones. The concentration of lead in the blood stream is determined by the relative rates at which it is absorbed and excreted or stored.

Interruption of lead absorption by the halting of exposure usually produces a gradual decrease in the amount of circulating lead. However, the return of lead from the bones to the circulation may maintain a toxic level for some time after exposure has been discontinued, and the sudden release of lead from the bones may produce an abrupt rise in levels of circulating lead, with the occurrence of toxic symptoms, even in the absence of further lead absorption. This phenomenon is generally encountered during periods of intercurrent illness, such as pneumonia, and may seriously impede recovery.

The amount of lead present in the circulation and in tissues other than the bones, may be estimated from the daily fecal and urinary lead excretion. The relation between the rate of lead excretion and the occurrences of lead intoxication is not absolute, but it is generally accepted that the excretion of more than 1.1 mg Pb in the feces in a 24-hr period, or the presence of a urinary lead concentration above 0.15 mg per liter is indicative of amounts in the blood and tissue sufficient to produce lead poisoning.

The recognition of early or mild lead poisoning is obviously an important means of preventing advanced or severe involvement. Lead poisoning can be detected best in its incipient state by regular and systematic investigation of exposed workers. The following investigations are useful in establishing the existence of lead poisoning.

1 Inquiry into the time and place of exposure to lead, with substantiation of conditions.
2 Careful examination of the worker for any symptoms or signs of lead poisoning.
3 Examination of the blood, with particular attention to the number of basophilic stippled red blood cells.
4 Analysis for lead in a chemically clean 24-hr specimen of urine or of a blood sample. If it is impractical to obtain a 24-hr sample, a reasonable estimate of the lead excretion can be made from a single specimen, preferably one passed early in the morning on arising. In calculating the total daily excretion, the relation of the sample volume to the 24-hr urine output should be estimated, and the total values figured on this basis. The finding of more than 0.10 mg Pb per liter of urine in a 24-hr specimen, or of a whole blood concentration in excess of 0.05 mg Pb per 100 ml in an individual with symptoms of lead poisoning, clinches diagnosis.

Industrial lead poisoning is prevented by reducing workers' lead absorption to the lowest possible level by the use of proper ventilation and housekeeping; and by regular periodic examination for evidence of lead intoxication of workers unavoidably exposed to these lowest possible levels. Such workers should be subjected to a careful physical examination, with elimination of unfit individuals. In addition, lead workers should be re-examined periodically while at work; the frequency of examinations may be varied according to the degree of exposure. Laboratory studies should be performed at least every six months, and oftener if the exposure is severe or if symptoms develop. Complete blood counts should be performed along with routine urinalyses and the special examinations outlined.

Workers with evidence of early lead intoxication should be removed from exposure until such evidence disappears. Most authorities believe that this waiting period can be accelerated by the use of deleading therapy under competent medical supervision. Indiscriminate, unsupervised deleading should be avoided. Individuals who show signs of lead intoxication repeatedly, after relatively slight exposure, should be transferred to other employment.

Recovery from lead poisoning is usually complete, leaving no disability of any sort.

Magnesium.[24–27] In the handling and use of magnesium and magnesium alloys, no toxic effects are caused by the metal itself; however, certain of the materials used in processing, particularly in founding, may impair health.

Magnesium is ordinarily used in the form of alloys that contain from 90 to 98% Mg. Since magnesium oxidizes at elevated temperatures and burns when heated above the melting point, protective agents or inhibitors are used in certain production operations. The protective agents may be used in several different ways in the foundry: (1) as fluxes on molten metal, (2) as agents added to molding sand, (3) as furnace atmospheres for heat treatment.

The fluxes used in melting and treating the metal may give rise to considerable amounts of acid fumes—principally hydrochloric acid—if the fluxes have picked up moisture from exposure to air or if hot sludge from the pots is exposed to the air. During periods of high humidity, the fumes can be very irritating to the nose and eyes, so that control measures may be necessary.

The common inhibitors mixed into the molding sand are sulfuric acid, boric acid, sulfur, and various fluorides. These fluorides will give rise to fluoride fumes. Practical experience has shown that concentrations in excess of about 10 mg per cu m, measured as HF, are likely to cause a prickling sensation in the nose, running of the nose, and slight nosebleeds. The nosebleeds may recur frequently for some days. Considerable apprehension has been felt that heavy exposures to fluoride fumes might cause fluorosis, a serious malady, but practical experience has not shown these fears to be justified. However, it may be too early (1947) to be sure that some fluorosis will not result, since many years may be required for the development of this condition. It would be common sense to insist that all workers who are exposed to fluoride fumes be examined routinely by a competent physician; and to design the magnesium foundry so that fluoride concentrations are kept below 3 mg per cu m, the ASA limit.

Sulfur dioxide may arise from the following sources: burning sulfur from the flux used in pouring operations; or sulfur dioxide gas used for flushing molds before pouring, and for maintaining suitable atmospheres in heat treating furnaces. This gas may readily cause acute irritation and pain in the nose, chest and eyes, but seldom causes serious injury. Difficulty is readily avoided by having adequate ventilation in the foundry and by using heat treating furnaces that are gastight.

It is possible to contract a mild type of metal fume fever from breathing freshly generated magnesium oxide fumes, but the required dosage is so heavy that it would seriously reduce visibility, and so far it has not been a problem.

Manganese.[28, 29] Poisoning by manganese is very rare and has been limited entirely to industry. Either breathing fine manganese dusts or swallowing manganese compounds in food or drink, can affect the central nervous system and produce disability that may be serious, total and permanent. Inhalation of manganese dust is the principal danger and, as far as is known, manganese poisoning does not occur if the dust from operations is controlled.

Manganese paralysis resembles Parkinson's disease (paralysis agitans) and can easily be mistaken for it, though the causes and sequelae of the two are entirely different. Manganese poisoning occurs only after prolonged and repeated exposures to finely divided dusts rich in manganese. Industrially such exposures are generally limited to the milling or grinding of manganese compounds, such as the oxides. Theoretically, it would be possible to breathe toxic doses in the manufacture or welding of manganese steels, of ferromanganese and spiegeleisen; but actually such poisoning has been virtually unknown up to the present. Special apprehension has been expressed for men welding manganese steels, but again, the results have not warranted these fears.

Safe concentrations in air have been set at ▮ mg (as Mn) per cu m, a limit easily maintained in industrial operations. Where ventilation is impracticable, occasional exposures to manganese dusts can be avoided effectively by the use of dust respirators.

Mercury.[30, 31] Industrial poisoning from mercury is seldom encountered at present. It may occur among miners working ores that contain native quicksilver, or among those engaged in refining the ore if old-fashioned furnaces with inadequate condensers are used. Laboratory workers have been affected through the careless overheating of mercury or electrical contacts, or through poor housekeeping. A possible source of mercury poisoning is the handling of wet-cell plates from the reclaiming of Zn:Hg batteries.

Acute mercury poisoning is well known and, though often caused by the accidental or deliberate ingestion of bichloride of mercury in the home, is almost never encountered in industry. Industrial mercurialism is a chronic, slowly progressing disease, produced ordinarily by the inhalation of small amounts of mercury vapor over a long period of time. It is characterized by muscular tremors (hatter's shakes), inflammation of the mouth with loosening of the teeth, an excessive flow of saliva, and psychic irritability and depression. One, two or all of the above symptom complexes may be present in a given instance.

Chronic mercurialism may be curbed by withdrawal of the worker from the contaminated atmosphere. Prevention depends on careful housekeeping methods to reduce the concentration of mercury to less than the accepted safe level of 0.1 mg per cu m of air.

Molybdenum.[32] Industrial exposure to molybdenum is encountered during nearly all stages in the mining, refining, and alloying of this metal. Miners are exposed to molybdenite dust, MoS_2; refiners to calcium molybdenite, and steel mill workers to molybdic oxide arising from hot billets of molybdenum steel during rolling. No injury has been reported from any of these exposures. Fairly extensive investigations of the toxicity of molybdenum, conducted at the Industrial Hygiene Laboratory of the National Institute of Health, reveal that the toxicity of molybdenum is of a relatively low order and that chronic poisoning by this substance is unlikely, since it is eliminated from the body fairly rapidly when exposure is discontinued. Reasonable care to avoid gross overexposure to molybdenum dusts or fumes should prevent effectively the occurrence of any ill effects from this substance.

Nickel. Nickel in the form of pure metal or nickel salts is toxicologically unimportant. No specific health hazards exist in the nickel industry, and no special precautions are necessary in handling this metal. Men engaged in nickel plating may develop an eczematous vesicular dermatitis ("nickel itch") affecting primarily the hands and arms, after contact with nickel sulfate or nickel cyanide solutions employed in the electrolytic bath. Some authors attribute this effect on the skin to the caustic action of nickel salts. Isolated and poorly substantiated reports of poisoning by nickel dusts are encountered in technical publications.

An exception to the general harmlessness of nickel compounds is nickel carbonyl. This poisonous gas (boiling point, 43 C) may produce effects ranging from headache, giddiness, unsteady gait and nausea to severe dyspnea, cyanosis, fever, cough, and delirium, followed by gradual recovery or death, either immediately or in three to eleven days. The Mond process for the production of pure nickel, involves the generation of nickel carbonyl and is performed carefully under controlled conditions that prevent escape of the gas.

Precious Metals. Industrial poisoning by the precious metals (gold, silver, platinum, palladium, iridium, osmium, rhodium and ruthenium) is virtually unknown. Serious poisoning by silver and gold have been reported frequently, following their administration as therapeutic agents in medicine; and it is theoretically possible that industrial poisoning by some of the precious metals could occur.

These substances are handled with extreme care, however, because of their intrinsic value, so opportunities for inhaling or ingesting their fumes or dusts are uncommon.

Selenium.[33] It is well established that the ingestion of selenium, as in fodder for cattle, can produce serious gastrointestinal damage not unlike metallic poisoning in general. Some industrial poisoning by selenium has been reported in the earlier technical publications, but it was limited largely to the refining of elemental selenium and tellurium from sludges collected in the electrolytic refining of copper. Garlic breath, like that from tellurium, has been ascribed to selenium, but it is certainly much less troublesome than with tellurium.

Industrially, selenium has not proved to be a toxic problem. Selenium is now being used extensively in the manufacture of photoelectric equipment and rectifiers. It is distilled under vacuum and condensed on disks that are handled manually. No toxic symptoms result if working conditions are good and suitable ventilation is provided.

Tellurium.[34, 35] The inhalation or swallowing of tellurium dusts or fumes can cause a garliclike breath that persists for some days or even weeks, after exposure has ceased. No other ill effects may be experienced and there is no evidence that organic injury necessarily follows. The feeding of very large doses of elemental tellurium can produce severe intestinal damage and even death, but in industry exposures are far too slight to cause real harm.

Industrial exposures to tellurium occur when pellets of the element are added to molten metals to produce alloys. Some tellurium is volatilized, oxidizes, and the fumes rise and mix with those from the ladle. Prevention of the garlic breath can be accomplished readily by means of proper ventilation, eliminating exposure to the fumes.

Thallium.[36, 37, 38] Industrial poisoning from thallium is infrequent. The symptoms are mild and disappear entirely after the termination of exposure. No deaths have been reported. The possibility of serious poisoning from the careless handling of thallium or thallium salts in industry, must be considered, however, because this substance is highly toxic. Many instances of serious or fatal poisoning following the accidental or therapeutic ingestion or external application of this substance, have been reported. One gram of thallium is considered capable of causing death in the average adult, and thallium salts have been shown to be more toxic than lead salts. The infrequent occurrence of industrial thallium poisoning is probably related to the relatively high cost of thallium and to the consequent care with which it is handled.

The characteristic sign of thallium poisoning is rapid loss of hair within a period of about three weeks after intake of the substance. This is preceded and accompanied by a variety of nonspecific symptoms from the gastrointestinal and nervous systems. Dermatitis and kidney damage may also occur. After the substance has been withdrawn, all symptoms disappear and hair returns.

Except for careful handling of thallium, no specific health measures appear to be necessary. Workers who develop symptoms in the gastrointestinal or nervous system, or whose hair suddenly begins to fall out, should be withdrawn from contact with thallium or its salts until the symptoms have disappeared.

Tin. Poisoning by tin is almost unknown. The innocuous nature of this metal is attested to by the complete absence of tin poisoning among the general population, all of whom ingest considerable quantities of tin dissolved from the linings of tin-plated cans.

Vanadium.[39, 40] Vanadium fumes are capable of producing moderately severe toxic reactions. Workers exposed to vanadium pentoxide, in factories producing vanadium and ferrovanadium, develop conjunctivitis, nasal irritation, and fairly severe bronchitis with an irritating cough. Gastrointestinal disturbances with nausea and vomiting may occur but are infrequent. Fumes containing vanadium anhydride are extremely irritating and produce a reaction similar to that experienced after the inhalation of zinc oxide fumes. No permanent ill effects and no nervous system involvement have been reported.

Zinc.[41–44] Poisoning from zinc is limited to two sources: (1) the ingestion of food or drink heavily contaminated with zinc and (2) the breathing of fairly heavy concentrations of freshly formed zinc oxide fumes. There is no evidence of any cumulative or additive effect from either of these sources.

Zinc oxide fumes are formed when metallic zinc is

heated to temperatures considerably below its boiling point (906 C). For instance, the vapor pressure of zinc is 0.1 atm at 720 C. Any process that produces this oxide is a potential source of metal fume fever, known industrially by various names, such as "spelter shakes", "zinc shakes", "brass chills", and "galvo". An attack of metal fume fever is characterized by a rise in body temperature, an increase in the white blood cell count, and a cough, varying from a trifling irritation to paroxysms that induce vomiting. The reaction is usually accompanied by a distinct sweetish taste. About eight hours after exposure, chills may occur and the body temperature may rise to 103 or 104 F. The temperature then gradually subsides and usually is normal the next morning, but the high white blood count (leucocytosis) persists for an additional 12 to 24 hours. The experience may remind the patient of his reaction to an inoculation against typhoid fever. It is probably because of the absorption of proteins from the respiratory tract, but just why zinc oxide should have this effect while other fairly inert oxides do not, is as yet unexplained. A similar but much less severe reaction follows the inhalation of heavy concentrations of magnesium oxide from burning magnesium ribbon. Reactions ranging from severe to fatal follow the inhalation of fresh cadmium oxide, but no reaction at all is induced by breathing freshly formed ferric oxide or aluminum oxide.

Metal fume fever from zinc oxide is an unpleasant experience that lasts only a few hours. There is no cumulative effect and the patient is not made susceptible to more serious respiratory maladies such as tuberculosis or pneumonia. It has been shown that temporary resistance to a second attack of metal fume fever is acquired as a result of the first attack and lasts apparently as long as the white corpuscle count remains elevated. This acquired resistance (not true immunity) probably explains the fact that severe attacks of metal fume fever are unlikely to occur on successive days.

Metal fume fever is most likely to trouble workers engaged in the smelting of zinc, the manufacture of zinc oxide and zinc powder, the manufacture of the brasses—especially those high in zinc—and the welding (gas or electric) of galvanized iron.

In the welding of ordinary steel, solid fume particles evolve to the extent of about 4% of the weight of the rods burned. Welding on galvanized iron produces more fume—about 9% of the weight of the rods burned. From these figures may be calculated the ventilation necessary to keep the total fume concentration (as weighable solids) below 30 mg per cu m, the figure adopted by the Navy and Maritime Commission in their Health and Safety Standards during World War II. However, this figure is not low enough to ensure good visibility for the crane operator in a large machine shop; 10 mg would be better.

In general, prevention of zinc fume fever is easy—keeping average concentrations to which workers are exposed below about 15 mg of ZnO per cu m per 8 hr. This specification works no special hardship on the manufacturer and is easily attained. For short exposure, respirators of a quality approved by the Bureau of Mines are entirely practicable.

Poisoning occurs sporadically from food or drink contaminated with zinc. The commonest cause is the dissolving of zinc by acid or fruit juice, such as lemonade. Obviously, liquid foodstuffs should not be stored in zinc or zinc-lined containers, but galvanized iron sheets are well adapted to the lining of refrigerators, bins for grain storage, water reservoirs and the like, for which they have been used for years.

There is no specific treatment for metal fume fever. Palliative measures, such as hot baths, hot drinks and the like, relieve the patient somewhat, but do not alter the course of the attack.

Poisoning by ingested zinc is self-limiting. Treatment consists of the general supportive measures employed in any severe gastroenteritis.

The Aluminum Industry

By Junius D. Edwards*

ALUMINUM as an element was discovered in 1825 and the commercial history of it covers only 60 years. It is one of the principal metallic products of the electrochemical industry.

Occurrence. The principal ore of aluminum, bauxite, comprises the hydrated oxides of aluminum, $Al_2O_3.3H_2O$ and $Al_2O_3.H_2O$, together with associated impurities, such as the oxides of iron, silicon and titanium. Bauxite is produced by the weathering and alteration of aluminum silicate rocks, and is widely distributed around the world, usually in tropical and semitropical regions, where the weathering processes have proceeded at an accelerated pace. At the present time, the principal supplies of bauxite come from the United States, Suriname, British Guiana, France, Hungary, Italy, Jugoslavia, Russia, and the Netherlands' Indies. Bauxite is thus not a rare ore, and its principal value, when delivered in refined form for the electrolytic production of aluminum, lies in the transportation charges and chemical refining costs incident to its purification. The bauxites used for the production of aluminum contain about 50 to 65% alumina; about four pounds of bauxite is necessary, therefore, to produce one pound of aluminum. It has been esti-

*Assistant Director of Research, Aluminum Research Laboratories, New Kensington, Pa.

mated that enough bauxite is in sight to supply the world with aluminum for the next several centuries.

Extraction or Refining Methods. In the electrolytic reduction of aluminum oxide, any impurities, such as the oxides of iron, silicon and titanium, are reduced along with the alumina. Therefore the alumina used is first refined by removal of these impurities. It is essential to start with raw materials of the highest purity, and this includes not only the alumina but the carbon electrodes and the fused electrolyte employed in the process.

The Bayer process is almost universally employed for the purification of bauxite. In this process the bauxite is digested with caustic soda solution, under pressure, and the alumina is dissolved out as a solution of sodium aluminate. The residue, known as "red mud", contains the oxides of iron, silicon and titanium, and is separated by settling and filtration. Aluminum hydrate is separated from the solution of sodium aluminate by seeding and precipitation and is converted to the oxide, Al_2O_3, by calcination.

The electrolytic reduction process is based on the discovery by Charles M. Hall that molten cryolite dissolves alumina, and that aluminum can be separated continuously from the molten solution at about 1000 C by electrolysis. The electrolytic reduction takes place in large cells that consist of a steel shell lined with carbon, forming an inner cavity in which the cryolite electrolyte is held. The carbon anodes, dipping into the electrolyte, introduce the current which separates the metallic aluminum electrolytically and provides the heat that keeps the bath liquid. Molten aluminum deposited on the bottom of the cell is withdrawn from time to time, as it collects. This primary aluminum of commerce ranges in purity to about 99.9%, depending on the care and skill with which the raw materials have been prepared and the reduction process carried out. Aluminum of purity as high as 99.99% can be produced by the Hoopes electrolytic refining process, in which aluminum is dissolved electrolytically from a molten aluminum-copper alloy and is deposited in a layer of pure aluminum, acting as cathode and floating on the molten electrolyte that separates the anode from the cathode layers. The production of a pound of aluminum requires about 10 kwhr of electrical energy, so cheap electric power is essential for the commercial production of aluminum.

Principal Products. The aluminum sheet of commerce, usually designated 2S, has a nominal purity of about 99.2%. It is, in fact, an alloy containing small amounts of iron and silicon, and its strength is substantially increased thereby. Another commonly used wrought alloy, known as 3S, contains 1.2% Mn. The principal elements used in the production of aluminum alloys are copper, silicon, manganese, chromium, magnesium and zinc. Since the invention of duralumin and the discovery and explanation of heat treatment effects in aluminum alloys, a series of heat treatable aluminum alloys has been developed. In certain wrought forms, tensile strengths above 80,000 psi are now obtainable. The alloys that can be heat treated are frequently referred to as the "strong alloys of aluminum" and greatly extend the field of application of aluminum.

Uses. Aluminum and its alloys can be worked and fabricated by the usual metal working processes, such as rolling, stamping, spinning, drawing, extruding, and forging, and can be produced in the form of castings by the sand, permanent mold, or die-casting processes. Except for magnesium and beryllium, aluminum is the lightest of the structurally useful metals. In the transportation field, it is not only the lightness of aluminum and its alloys, but the high mechanical properties obtainable by alloying and heat treating, which make aluminum suitable for light-weight structures.

Aluminum and its alloys can be joined by riveting, welding and brazing. Welding is done by torch methods, or electrically by arc and electric-resistance welding methods. There are some limitations, however, to the welding of heat treated alloys, because the heat of welding removes some of the effects of heat treatment.

Aluminum has good electrical conductivity, about 61% that of copper, volume for volume; weight for weight, the conductivity of aluminum is about double that of copper. High electrical conductivity, combined with good resistance to weather and with adequate mechanical properties, accounts for the use of more than 1,250,000 miles of aluminum cable, reinforced with steel.

Aluminum is also a good conductor of heat. This property is utilized in such varied applications as cooking utensils, and pistons and cylinder heads for internal combustion engines.

Aluminum is a good reflector for radiant energy throughout the spectral range, from ultraviolet through the visible range and into the infrared. It is being employed in thin films on the reflectors of the most modern telescopes, it is widely used for light reflectors in the illuminating industry, and its high reflectivity for infrared radiation is giving it a unique field of usefulness for thermal insulation. The

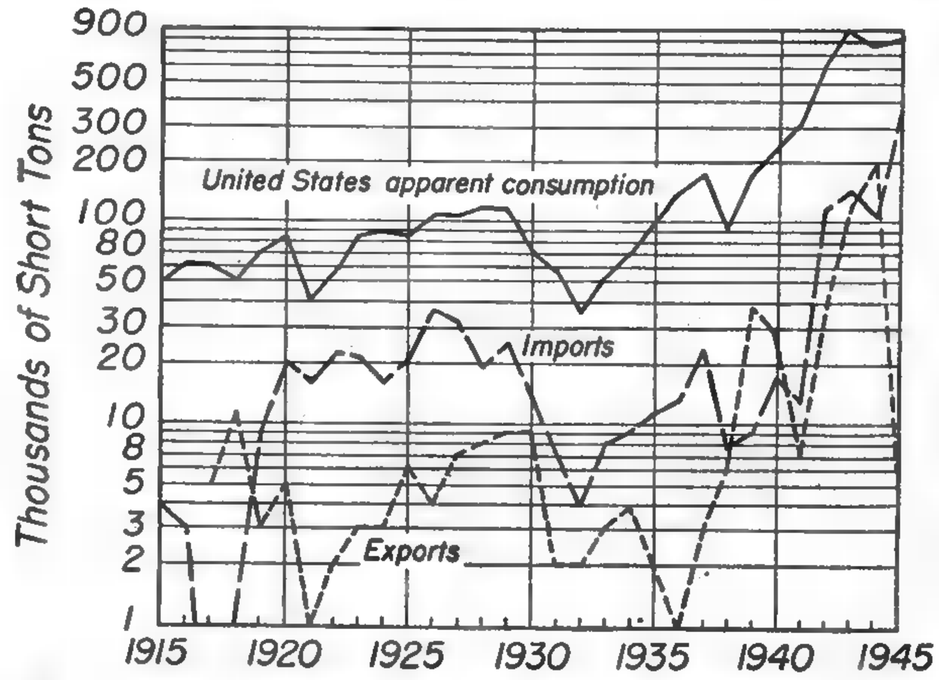

Fig. 1 Trends in imports, exports, and apparent consumption of aluminum, 1915 to 1945. (U. S. Bureau of Mines Minerals Yearbook, 1945)

usefulness of aluminum as a practical light reflector has been extended by the Alzak process, which includes electrolytic brightening to develop maximum reflection, coupled with an electrolytic oxide coating to provide a glasslike, transparent, weather-resistant and cleanable surface. In the thermal insulation field, aluminum foil, with its high reflectivity for thermal radiation and its low radiating power or emissivity for the same type of radiation, gives a high insulating effect to a structure comprising sheets of aluminum foil separated by air spaces.

In contact with moist air aluminum forms a thin, impervious film of oxide, which helps protect it against further attack. Aluminum can be electrolytically oxidized to give it a thicker oxide film of great hardness and resistance to corrosion. These anodic oxide films can be colored by the

absorption of dyes or by impregnation with inorganic pigments.

Aluminum has a high heat of combustion, and this affinity for oxygen is the basis of the thermit welding process, in which the reaction between finely divided aluminum and metallic oxides, such as iron oxide, produces a molten ferrous alloy at a high temperature.

Another chemical use of aluminum is as a deoxidizer in the manufacture of iron and steel. Gas-free steel ingot is produced by exploiting the great affinity of aluminum for oxygen.

In finely divided flakes aluminum makes an excellent paint pigment, supplied as either aluminum powder or aluminum paste. Aluminum paint made with this pigment

forms a durable and protective coating for both metal and wood. Relatively impervious to penetration by moisture, and opaque to sunlight, this coating conceals and covers well, remaining protective over extended periods, even under conditions of severe exposure.

Statistics. During the war, aluminum production facilities were expanded sevenfold to supply the material needs of the Air Force, Army and Navy. In the postwar era much less aluminum will be needed for aircraft and other military applications. However, civilian uses for aluminum will undoubtedly show substantial increases, because manufacturers and metal workers have gained extensive experience and familiarity with this metal during the war. Research and development have provided a sound fundamental knowledge of aluminum, on which to base these extended applications of the metal. Statistics regarding the trend in consumption and price of aluminum for the period from 1915 to 1945 are given in Fig. 1 and 2.

The pattern of postwar aluminum consumption has differed significantly from the prewar period; the principal change has been in the increased use of aluminum for building construction. One producer (Alcoa) reports the following shipments for 1946, according to industries:

Aluminum Consumption in 1946

Building products	18%
Transportation (land, sea and air)	14
Cooking utensils	11
Machinery (general and electrical)	6
Household appliances	6
Power transmission	5
Aluminum fabricators for further processing	25
All other uses	15

The Production of Finished and Semifinished Aluminum Alloy Castings

By H. J. Rowe*

ALTHOUGH the properties and inherent characteristics of the aluminum alloys themselves account for the use of aluminum castings in many applications, in other instances the variety of commercial processes by which such alloys can be cast provides important economic advantages. Selection of the most satisfactory casting process became especially important during the war, because of the effect on conservation of production man-hours, machining man-hours and materials. Judicious selection is equally important today because of the effect it can have on the cost of producing a particular item.

Casting Processes

The selection of the casting process best suited to any particular application depends on both technical and economic considerations; that is, on such features of functional design as the size and shape of the part, limitations of section thickness, the dimensional tolerances desired, and the surface finish required. The number of parts required and the amount of subsequent machining and finishing are also factors to be considered. Because each casting process possesses certain distinctive design requirements, it is easier to design a part to be made by a particular process than to modify it later. A designer can benefit greatly by determining the requirements of the process, preferably after consultation with the ultimate producer, before setting up the design.

Sand Casting. Because it is widely adaptable, the sand-casting process is still the best known and most frequently used. It is employed for production in small quantities and for production of parts requiring intricate coring, as well as for production of large parts. Castings weighing from a few ounces to 500 lb are common products of the sand foundry and castings weighing as much as 7000 lb have been produced successfully.

The sand-casting process for production of aluminum alloy castings differs in no essential way from that used for production of castings made of other metals, both nonferrous and ferrous. To produce the expendable sand mold, a suitable pattern is employed, with the required allowances for shrinkage and subsequent finishing. When cores are required, they are produced in core boxes and it may be necessary to provide core driers. Such equipment is somewhat lower in initial cost than equipment for certain of the other processes discussed later, but sand-casting equipment provides a more limited life. Production rates are controlled by the type of pattern equipment as well as molding equipment, and may range from a few parts per day for large castings using loose pattern equipment, to several hundred per hour for small castings using metal match-plate pattern equipment.

The minimum thickness of section that can be cast in aluminum depends largely on the size, pressure requirements and intricacy of design of the casting. Although sections of the order of ⅛ in. have been satisfactorily provided in small sand castings, $\frac{3}{16}$ in. is generally considered the minimum for castings of small and medium size.

The surface of sand castings will vary in smoothness, depending on the physical characteristics of the sand. Relatively smooth surfaces can be obtained with fine sand, but the use of such sand is limited to rather small castings. For larger castings somewhat coarser sand is desired, because the increased permeability of the mold makes for a sounder casting. In general, aluminum sand castings have smoother surfaces than sand castings of the other metals.

Dimensional tolerances in sand castings will vary with the size of the casting, the type and accuracy of pattern equipment, and the molding technique used. Tolerances of plus or minus $\frac{1}{32}$ in. can generally be maintained for small castings, but greater tolerances are required for larger castings. Hence, sand castings must normally be machined to meet close dimensional tolerances, and allowance for such machining is necessary. Normal practice is to provide about ⅛ in. for such finishing on small and medium-sized castings. Large castings usually require ¼ in. or more as allowance for finishing, particularly on surfaces cast in the cope of the mold.

The sand-casting process permits the use of a number of aluminum alloys, providing a variety of physical and mechanical properties, in both the as-cast and heat treated conditions. (*See* pages 824 to 840.) The selection of alloy, although normally influenced by these properties, should also take casting characteristics into consideration. These vary sufficiently to have frequently an important influence on the cost and utility of the final part. Such factors as hot shortness, pressure tightness, tendency toward solidification shrinkage, and susceptibility to gas absorption are frequently controlling factors in the selection of an alloy. The most common of the sand-casting alloys are rated in Table I with regard to these characteristics.

Casting in Permanent Molds. Castings produced by the permanent mold process, or gravity die-casting process, as it is called in England, are known for their metallurgical superiority. For this process, metal molds and cores are used; the casting alloy is poured into the mold cavity under a normal gravity head, as it is in the sand-casting process. A variation, known as the semipermanent mold process, employs dry sand cores instead of metal cores. This difference greatly increases the possible applications for the permanent mold by overcoming many of the restrictions that

*Chief Metallurgist, Castings Division, Aluminum Company of America, Pittsburgh

are imposed on the design by metal cores. The chill imposed by the metal mold results in a refinement of grain and reduction in porosity in the final castings, with a consequent substantial improvement in the strength as compared with that of similar sand-cast parts. Permanent mold and semipermanent mold parts weighing from a few ounces to 20 lb are common foundry products, but permanent mold parts weighing as much as 250 lb, and semipermanent mold castings weighing as much as 500 lb have been produced.

Mold equipment usually consists of two or more parts suitably hinged or mounted on slides for ready opening and closing. This equipment is constructed from a good grade of dense cast iron and has cavities machined to the desired contour. Metal cores, when required, are usually machined from alloy steel. Sand cores are of the same general type as those used for sand castings and require the same material and equipment for production. The cost of such molds depends on their complexity and the casting tolerances desired. Normally this cost exceeds that of the best pattern equipment but can be justified where requirements of production are sufficient. Rates of production are controlled by the time required for the metal to solidify and the complexity of the mold operation. For small simple parts, permitting the use of multiple-cavity molds, production rates as high as 100 parts per hr can be obtained, although in specific instances even higher rates have been attained.

As with sand castings, it is difficult to state the minimum thickness of section that can be provided by the permanent mold process, because of the effect of size and intricacy of

Table I. Relative Casting Characteristics of Common Alloys for Sand Casting
Numbered in order of preference. (1, Best)

220	10% Mg	3	5	5	3
355	5% Si; 1.3% Cu; 0.5% Mg	1	1	1	2
356	7% Si; 0.3% Mg	1	1	1	2

the casting. Although sections of the order of $\frac{1}{10}$ in. can be provided in certain castings, $\frac{1}{8}$ in. is usually considered the minimum. The minimum diameter of holes cored with metal cores is considered to be $\frac{3}{8}$ in., but holes as small as $\frac{1}{4}$ in. in diam are produced in some parts.

With proper control of mold coatings, which are essential for this process, casting surfaces can be produced superior to those provided by sand. Often these surfaces do not require further processing.

For minimum mold and casting cost, dimensional tolerances and draft allowances should be as liberal as possible, particularly where close limits are not required. Possible tolerances depend on the size and complexity of the casting and the location of the dimension involved, in relation to moving members of the mold. In general, lower tolerances are practical than those possible with sand castings; plus or minus 0.020 in. is common for small castings. Tolerances are usually figured as plus or minus $\frac{1}{64}$ in. for the first inch or less, plus 0.001 to 0.002 in. for each additional inch of length, depending on whether the dimension is affected by moving parts of the mold. With such tolerances and the smoother surfaces provided, allowances for machine finish can also be reduced for permanent mold castings. A finish allowance of $\frac{1}{32}$ in. to $\frac{1}{16}$ in. is generally adequate, depending on the size of castings.

As with sand castings, the alloy for permanent mold castings should be selected after a consideration of the foundry characteristics, as well as of the physical and mechanical properties. (*See* pages 824 to 840.) Because metal molds resist the contraction of the casting more than sand molds, freedom from hot shortness is one of the essential requirements in selecting an alloy. Pressure tightness and tendencies toward solidification shrinkage are among the other characteristics to be considered. Porosity resulting from absorption of gas is not usually a problem with permanent mold castings, since the chill imposed by the mold results in the metal retaining more gas in solution and effecting a finer dispersion of any gas that is released. Table II rates these characteristics for the common permanent mold alloys.

Table II. Relative Casting Characteristics of Common Alloys for Permanent Mold Casting
Numbered in order of preference. (1, Best)

Die Casting. Another casting process of importance for aluminum alloys is the die-casting process, known particularly for the accuracy and uniformity of reproduction that it provides. In this process a metal mold or die and metal cores are used, either or both of which may be water-cooled. The molten metal is injected into the die under pressure. Two general methods are used to accomplish this: air injection, using so-called "gooseneck" machines; and metallic plunger injection, using so-called "cold chamber" machines. Injection pressures in gooseneck equipment are limited to about 750 psi, while in cold chamber equipment, pressures of 3000 to 15,000 psi are commonly used, although pressures exceeding 20,000 psi have been employed. For illustrations of gooseneck and cold chamber machines, see the article on "Casting and Production of Zinc Alloys", page 1078.

The size of die castings is limited only by limitations of casting design and equipment, improvements in which are being made continually. Castings have been produced that weigh from a fraction of an ounce to 20 lb with over-all dimensions of 36 by 12 by 9 in. Dimensions in one direction may exceed these considerably, since castings up to 84 in. in length have been produced.

The die-casting process itself, as employed with aluminum alloys, is similar in most respects to that employed for the die casting of other metals. With aluminum alloys, heat treated alloy steel dies are used, the designing of which is best done by trained engineers who are experienced with aluminum die-casting problems. There is no substitute for this experience in providing a satisfactorily operating die assembly. The cost of this equipment will vary with the size and complexity of the casting, and often is no greater than the cost of equipment for other casting processes for equal daily production. Production rates for die castings also vary with size and intricacy of casting and dies, and size of machine used; large machines operate more slowly than small machines. With both gooseneck and cold chamber machines, operating speeds up to 150 cycles per hr may be attained if the part is simple and the die is of small or medium size. It is frequently practicable to produce a number of castings in a die simultaneously, thereby permitting increased piece production per cycle.

Because of the nature of the die-casting process, sections can be provided that are somewhat thinner than can be made with other casting processes. In fact, it is generally preferable to maintain sections in die castings as thin and uniform as possible, consistent with the size and complexity of the casting, the alloy used, and the requirements of strength and rigidity. Under favorable conditions, castings having a major dimension of 6 in. can be produced with sections of 0.045 in. in thickness. For castings with a largest dimension of 15 in., a section thickness of 0.080 in. is about minimum. Larger castings require somewhat heavier sections, but sections thicker than 0.150 in. are rarely needed for satisfactory castings.

The die-casting process permits the casting into position of inserts of various metals to serve as bushings, studs and liners. Holes and cavities can also be provided by coring, thus reducing machining operations and making for lighter castings with superior metallurgical properties as a result of the increased chill provided by the steel cores. The use of such cores requires a draft allowance, minimum requirements for which are given in Table III, together with the maximum limitations of depth usually imposed.

Table III. Draft and Depth Limits for Cores

Approx Diameter of Hole	Draft Required on Diameter per Inch of Depth	Maximum Depth
1/10 in. (min diam) to 1/8 in. incl	0.020 in.	3/8 in.
1/8 in. to 1/4 in. incl	0.016 in.	1/2 in. to ▮ in. depending on size
1/4 in. to 1 in. incl	0.012 in.	2 in. to 8 in. depending on size
More than 1 in.	0.012 in. to 0.030 in. (depending on size and design)	Depends on size and design

The surface smoothness of die castings is superior to that of any other forms of aluminum casting, a condition that makes for low-cost polishing operations. The surface detail possible with die castings is excellent; in fact the reproduction of engraved or ornamental designs is one of the outstanding advantages of the process.

Tolerances as low as plus or minus 0.0015 in. per lineal inch of dimension, but not less than plus or minus 0.002 in. on any dimension, are provided commercially by die castings. On large castings, this tolerance can be reduced further to plus or minus 0.0010 in. for each additional inch over 10 in. Dimensions affected by the parting line of the die or other die parts movable with respect to each other, usually require an additional tolerance of 0.010 in. or less, generally on the plus side.

With such dimensional accuracy, smooth surfaces and ability to cast external threads and core holes, subsequent machining of die castings is reduced to a minimum. The rapidly chilled surface skin of die castings accounts for their excellent mechanical properties, and makes excessive machining actually undesirable, since the result will be a disproportionate loss in strength. Excessive machining may also reduce the resistance of the casting to leakage under pressure.

As with the die design, the selection of alloy for die castings is best left to the producer of die castings, whose experience will permit him to recommend materials that will present the fewest production problems and insure the most satisfactory castings. Not all alloys suitable for other casting processes are satisfactory for the production of die castings. Many alloys are too hot short or do not have mold-filling characteristics satisfactory for die casting; others introduce operational problems that would affect the ultimate cost of casting. The most important of these characteristics are rated in Table IV for the common die-casting alloys. Their mechanical and physical properties will be found on pages 824 to 840.

Table IV. Relative Casting Characteristics of Common Alloys for Die Casting

Numbered in order of preference. (1, Best)

Alloy	Nominal Composition	Hot Shortness	Mold-Filling Capacity
13	12% Si	1	1
43	5% Si	2	3
85	5% Si; 4% Cu	3	2
218	8% Mg	4	4
360	9.5% Si; 0.5% Mg	1	1
380	8.5% Si; 3.5 Cu	2	2

Casting in Other Metal and Refractory Molds. Several additional casting processes adaptable to aluminum alloys have attained commercial significance. Most of these are modifications of the previously mentioned processes designed to provide improved casting tolerances. As such, these processes took on important roles during the war, since they provided a source of small precision castings with a minimum of man-hours spent in machining.

Because the initial cost of castings produced by these processes is higher than that of castings produced by the more common processes, their applications during postwar years will probably be limited. However, they do offer certain advantages which cannot always be provided by the other processes and which will undoubtedly dictate their use for certain castings of a specialty type.

Casting in Plaster Molds. The process of casting in plaster molds, perhaps the most common of the specialty processes, is a refinement of the sand-casting process. In plaster molds, the normal molding sand is replaced by refractory materials providing smoother surfaces and greater accuracy in the mold. Gypsum plasters are the most common molding materials for aluminum alloy castings. Molds of such materials must be processed subsequently by heating to remove excessive water and to put the plaster in a condition to receive metal. A mold is capable of producing only one casting, after which it is discarded. The process is generally confined to small castings that weigh less than about 2 lb, but considerably larger castings have been made.

Metal match-plate pattern equipment and suitable metal core boxes, if cores are required, are essential to this process for best results. Such equipment, because of the accuracy generally required, costs more than similar equipment for sand castings, but less than that required for permanent mold castings. For larger production jobs, such equipment can best be used in a mechanized setup permitting production rates nearly equal to those of the permanent mold process. Metal for such molds is usually poured under gravity conditions, although moderate pressures are sometimes applied after pouring, in order to provide improved casting detail.

The refractory nature of the molding material used for this process results in slower solidification of the metal than in normal sand or metal molds. This is an advantage in that it permits casting of sections thinner than practicable in sand or permanent molds and approaching those of die castings. It is, however, a disadvantage in that it makes for lower mechanical properties than are provided under conditions of greater chilling. Because of segregation in some alloys under conditions of slow cooling, the type of alloy adapted to this process is also limited. Aluminum-silicon alloys, such as No. 43 and 355, have found most favor.

Plaster mold castings have a surface finish superior to that of sand castings and generally comparable with the finish on permanent mold castings or even superior. The tolerances provided are as good as those possible with permanent mold castings and often approach those of die castings. For this reason, machining requirements are generally low; the higher cost of casting is frequently offset by elimination of machining costs.

*Precision Investment Casting.** This process is an adaptation of the so-called "lost-wax" process commonly used for the casting of jewelry from the precious metals. It affords the intricacy of design possible in sand castings with precision approaching that of die castings. A refractory type of mold or investment is used, ordinarily of gypsum plaster for the casting of aluminum. An expendable wax pattern is employed instead of the usual permanent pattern. The heating of the mold to develop the required condition to receive metal, melts out the wax pattern, providing the required mold cavity. Molds can be used only once, since they are broken up to remove the casting. At present the process is normally confined to very small castings, although statuary of considerable size has been produced by this method for a number of years.

A master mold for the production of the wax patterns is the essential equipment required for precision investment casting. When considerable production is involved, this master mold is preferably of metal and designed to permit production of the wax patterns by injection methods. Although the initial cost of this equipment is frequently lower than that of equipment for the other casting processes, the use of the equipment and subsequent production of the molds requires skilled operators, thus making for a final casting cost exceeding that of other types of castings. This type of casting is usually poured to provide metal under pressure, using the centrifugal process or vacuum

* For a general description of this process, see the article on page 54.

or some means of applying pressure after the metal is poured. The production rate for precision investment castings is relatively slow compared with other processes.

As with other casting methods employing refractory materials, casting sections approaching those of die castings can be produced. Because most castings produced by this method are of very small size and light section, the effect of the slow cooling imposed by the mold is not sufficient to affect greatly the mechanical properties or choice of alloy. Most of the aluminum casting alloys can be used for the small castings. For larger castings, it is preferable to use aluminum-silicon alloys, such as No. 43, 355 or 356.

Depending on the accuracy of the master mold and the selection and control of the wax and mold materials, this process can yield castings of great dimensional accuracy, often approaching the accuracy of die castings; and because there are no moving members in the mold or die to interfere, accuracies in some instances may be superior. The use of pressure to fill the mold cavity insures a sharpness of detail approaching that of die castings; hence, subsequent machining is reduced to a minimum.

Centrifugal Casting. This process consists of pouring molten metal into a revolving mold, utilizing the centrifugal force developed to force the metal into the mold cavity. Centrifugal casting has been popular for various ferrous and nonferrous alloys because the metal is cleansed of oxides and inclusions by centrifugal action, and improved mechanical properties result. Because of the small difference in specific gravity between the usual oxides and inclusions associated with aluminum alloys, the possibility of a similar separation by centrifugal action is limited. Whether mechanical properties can be improved beyond those provided by the normal casting procedures is therefore questionable. Centrifugal casting of aluminum alloys has seen limited use to date (1947) and it remains to be shown whether this process offers anything further than a means of pouring metal under pressure.

Centrifugal castings are of three general types: (1) true centrifugal castings that are substantially symmetrical around an open center and are rotated about the central axis; (2) semicentrifugal castings, which are similar to (1) and are also rotated about the central axis, but in which central cores are used to form the contour of the bore; (3) centrifuged castings that are unsymmetrical or without a central hole and are rotated in a horizontal plane along the perimeter of a circle concentric with the axis of rotation. Molds for any of these types may be of sand, refractory or metal, although the lower strength of sand molds limits their use. Metal molds are preferred for high production but refractory molds of material such as gypsum plaster, have proved satisfactory for small castings.

Equipment requirements for molds into which metal is to be cast centrifugally are essentially the same as for similar molds used for comparable gravity castings; therefore the costs of equipment should be much the same. The limits of size for centrifugal castings must still be determined, since most production to date (1947) has been confined to rather small castings.

Because of the effect of the metal pressure, resulting from centrifugal force, on section thickness, smoothness of surface and sharpness of detail, centrifugal castings should provide tolerances somewhat superior to those produced in similar mold equipment under gravity. Of particular importance would be the possibility of casting thin sections at low metal temperature, a condition that should reflect favorably on mechanical properties. Alloy limitations, if any, have not been established, and any of the standard casting alloys for the comparable gravity process would be considered suitable. In producing true centrifugal castings, alloys that are normally considered hot short should be cast with less difficulty.

General Casting Considerations

In addition to those casting considerations that have been specifically mentioned under the various casting processes, there are other general considerations that apply to all processes. Knowledge of these should be helpful when the design, manufacture and use of castings are considered.

Casting and Equipment Design. Some features of design necessitated by the service requirements or functional requirements of a casting are discussed on page 523 in this Handbook. However, other features, if properly considered during the designing of a cast part, will aid the foundry in obtaining higher quality and greater economy. Most of these can be established only by discussion with the ultimate producer of the casting, since they may depend on his particular type of equipment and production methods. Usually the functional requirements of a casting can be achieved by several designs, and a review of these by the foundry, prior to the setting of the final design, will frequently permit great savings in equipment and process.

Certain of the characteristics of aluminum alloys simplify casting and equipment problems; other characteristics make necessary the use of practices that differ from those used with other metals. The low specific gravity of aluminum is an advantage because it produces lower mold pressures and, in the making of sand castings, permits lighter sand ramming and lighter mold equipment. On the other hand, the low density makes it somewhat more difficult for aluminum alloys to rid themselves of their oxides or to drive off mold gases than it is for the heavier metals; therefore in gravity cast molds, permeability and venting of molds assume greater significance.

The strength of aluminum alloys is quite low at temperatures just below that at which the metal solidifies. This characteristic is called "hot shortness" and, as indicated previously, will vary with alloy composition. Although selecting a suitable alloy will overcome problems of hot shortness in many instances, it is desirable that designs and casting methods should minimize any resistance to contraction while a casting is passing through the range of temperature associated with hot shortness.

The relatively high solidification shrinkage of approximately 3.5 to 8.5% for aluminum alloys also requires consideration from the standpoint of design and equipment. Means of compensating for this reduction in the volume of metal are required and can be facilitated if this characteristic shrinkage is considered during the design stages.

Although all the aluminum casting processes permit the use of metal inserts within certain limitations, the permanent mold and die-casting processes are particularly adapted to their use. Cast iron or steel are the most suitable materials for such inserts, but copper and brass are commonly used when proper care is taken to prevent their solution in the molten aluminum. The use of inserts often permits a design that is more economical to produce as an integral part than as an assembly of several parts.

Melting and Handling of Metal. Melting is the initial step in the production of all types of castings. Melting equipment and melting and handling procedures can reflect greatly on casting procedures as well as on the final quality and cost of the castings. Therefore the selection of equipment and the establishment and control of procedures must be given careful consideration.

Certain characteristics of aluminum alloys are important factors in establishing requirements of equipment and procedure. Molten aluminum alloys possess a marked tendency to absorb hydrogen. The liberation of this hydrogen during the freezing of the metal in a casting is the cause of the so-called pinhole or gas porosity. In the melting or handling operations, any source of water vapor particularly, or of any other material that will form hydrogen as a result of chemical reaction with the molten metal, is a potential source of gas porosity. Important sources of gas are moisture in the atmosphere above the metal, moisture formed as a product of combustion of the melting fuel, and moisture or other hydrogen-forming material combined with, or absorbed in, the oxide film on the surface of the metal to be melted.

Several factors are important in the control of the gas content of aluminum alloys. Evidence indicates that the gas absorption will be greater, the higher the temperature of the metal, the longer the time it is held at temperature, the higher the absolute humidity of the atmosphere, and the more direct the exposure of the molten metal to products of combustion. The envelope of oxide which always surrounds the metal, has been found to offer considerable protection against gas absorption and, as long as this envelope remains unbroken, the absorption of gas is relatively

slow. Preheating the metal to be melted, to about 900 F prior to submerging it in a molten bath, effectively eliminates gas resulting from any hydrogen-forming materials on the surface. Consideration of these factors provides the means of controlling the gas content of the metal. Use of low melting temperatures, avoidance of long holding periods, minimum agitation of the molten metal, control of combustion products, and preheating of solid material before melting, will generally provide metal sufficiently low in gas content for the various casting applications.

A second characteristic of aluminum alloys, important from the standpoint of melting and handling, is the readiness with which they combine with oxygen to form oxides and dross. The formation of an oxide envelope during melting is an advantage in preventing further oxidation of the metal and, as mentioned above, in preventing rapid absorption of hydrogen. Also, because of this protective oxide, it is not generally necessary, during the melting of aluminum alloys, to use a flux cover such as must be used with certain of the other metals. However, dross that is formed as a result of oxidation may be trapped in the molten metal and, if not removed, may constitute a defect in the final casting. Therefore, excessive agitation of the metal should be avoided while the metal is molten in the furnace, as well as during any transfer from furnace to pouring ladle, or during the pouring operation.

Furnace equipment for remelting aluminum alloys for foundry use should be selected not only on the basis of capacity and efficiency, but also from the standpoint of a design that will provide a minimum of gas absorption and of oxidation. The furnaces that best fulfill these requirements are the ones in which the metal is melted without coming in contact with the heating medium. Pot-type furnaces, heated indirectly by gas or oil, are the most commonly used. Cast-iron pots, suitably coated with a protective wash, are generally used with such furnaces, although nonmetallic pots of graphite or various vitreous and refractory materials offer certain advantages for some conditions of melting. Pots of these nonmetallic materials are particularly useful for melting aluminum-silicon and aluminum-magnesium alloys, where a minimum of iron pickup is desired. Electric induction furnaces, developed specifically for aluminum, are being employed in some foundries. Such furnaces provide desirable melting conditions for many foundry applications.

Proper control of temperatures is necessary for metal of the highest quality. As mentioned previously, both gas absorption and oxidation increase with the temperature of the molten metal. Holding the metal at even moderately high temperatures also tends to coarsen the grain structure of the resulting casting; the higher the holding temperature, the shorter the time required to produce an inferior structure. Therefore, to insure obtaining metal of maximum quality, melting or holding furnaces should be equipped with suitable thermoelectric devices for controlling or indicating temperature. See the article "Pyrometry", page 174 in this Handbook.

Under proper conditions of melting, fluxing of the metal while it is molten is not always necessary; hence, when a flux is used, it should be considered a supplement to good melting and handling practices, and not an agent to offset the effects of an otherwise inferior foundry technique. For the most part, the fluxing of metal for foundry use is confined to situations that require reduction in oxides and gas beyond that provided by ■ good melting and handling practice. Various solid and gaseous fluxes are used for this purpose; aluminum chloride, zinc chloride, chlorine gas, and nitrogen gas are among the materials most commonly used. The solid materials are usually prepared in aluminum foil capsules and immersed near the bottom of the melt. The gaseous materials can be introduced by means of carbon or refractory tubes extending to the bottom of the melt. In using any of these fluxes, care must be taken to insure that they are dry and, where necessary because of their toxic nature, to provide adequate ventilation. Various proprietary fluxes for aluminum are used to some extent; the most common of these fluxes act as a drying agent for the surface dross, facilitating removal of dross during skimming.

Finishing of Castings. One of the important economies to be realized by the use of aluminum castings results from the ease with which they can be finished. The light weight, which facilitates handling during the finishing operation; the smoothness of the cast surfaces and absence of burnt-in sand; the nonabrasive character of the metal; and the ease and speed with which the metal can be trimmed, machined or ground—all make for economy in finishing. Operations normally performed in the foundry, consist of core knock-out (where sand cores are involved), chipping, die trimming, sawing and grinding to remove gates, and polishing and abrasive blasting when required for surface appearance. Standard tools for use with aluminum are available for this purpose.

Aluminum castings are also excellently suited for various ornamental and protective finishes. Ordinarily applied by the manufacturer of the finished product, such finishes are produced by mechanical, chemical or electrochemical means, depending on the ultimate effect desired. Mechanical finishes, produced by polishing, buffing or satin finishing, are applied with the ordinary types of polishing equipment. Other desirable finishes may be obtained with rotating wire brushes, fiber bristle brushes, tumbling with various abrasive and cleaning mixtures, and hand rubbing. These and other types of finishes are discussed in detail in another article (*see* page 789).

Machining of Castings. Aluminum alloy castings are readily machined, although for best results certain practices must be followed that are different from those generally used for other metals. Details concerning the machining practices recommended for aluminum will be found in the article on page 786.

Heat Treatment of Castings. The mechanical properties of many of the aluminum alloys can be greatly improved by heat treatment and a number of such treatments have been developed for castings (*see* page 775). In addition, heat treatments are available that provide improved dimensional stability by reducing stresses and growth. These treatments are applied principally to sand and permanent mold castings, although castings produced in refractory molds or by centrifugal casting can be so treated when desired. Heat treatment finds limited application with die castings because of the blistering that may occur as a result of gas holes, and the possible loss of desired dimensional accuracy.

The Production of Aluminum Alloy Ingots for Working

By W. T. Ennor*

THE production of aluminum alloy ingots that are subsequently to be forged, extruded or rolled, involves converting aluminum and alloy pig, ingot and scrap to molten metal of satisfactory chemical composition and metallurgical quality, and casting this metal into ingot molds.

Melting. Melting equipment and practices are influenced by several inherent characteristics of aluminum: the low density, high specific and latent heats, relatively low melting temperature, high reflectivity, rapid oxidation to form a protective film, solution of hydrogen by molten aluminum, small differences in density among molten aluminum, oxide film and refractory inclusions, and the solubility of iron and silicon in aluminum.

Equipment. Many types and sizes of melting furnaces are in common use, but the fact that ingots for working are normally produced in large tonnages of standard shapes and sizes has resulted in a trend toward furnaces of

*Metallurgical Department, Aluminum Company of America, Pittsburgh

high capacity and melting room layouts designed for continuous operation. Auxiliary holding furnaces or crucibles may be provided so that casting can be continuous, even though melting requires a recurring cycle of charging, melting, stirring and fluxing.

Reverberatory melting furnaces of 10,000 to 50,000-lb capacity are most commonly used. The fuel may be gas, oil, coal or coke. Smaller furnaces may be of either the reverberatory or the pot type. These pot furnaces are heated by combustion of gas or oil between a refractory shell and inner container. Cast-iron, graphite or refractory pots may be used.

Furnaces of the radiant type are little used because the high reflectivity of aluminum causes poor efficiency. Electric induction furnaces have a number of theoretical advantages and are receiving increased attention.

Refractories for furnace lining must be selected with careful consideration of wearing tendencies that result from the charging and furnace cleaning procedures employed; of thermal shock induced by the heating and cooling cycles used; and of the importance of avoiding silicon pickup in the alloys melted.

Cast-iron or steel tools are used for charging the furnace, stirring and skimming. Cast iron is dissolved by molten aluminum at a slower rate than steel, but in order to decrease solution, either metal should be coated periodically with a slurry of lime, mica, or other similar material.

Specialized auxiliary furnaces for melting finely divided and dirty scrap, and equipment for handling and recovering aluminum from skimmings, are found in most melting rooms producing ingots for working.

Melting and Alloying Practices. The major operations to be carried out in melting are charging, melting, stirring and fluxing. A batch system may be used whereby the entire furnace charge is melted and poured off as a unit; but continuous or, more accurately, semicontinuous melting, where a portion of the melt is removed periodically and replaced by a new charge, is a less expensive and more common practice. In order to shorten the cycle in the melting furnace and to provide a quiet, properly treated bath for withdrawal to a casting unit, metal may be transferred to a holding hearth in the same furnace or to a separate furnace, immediately after stirring or fluxing.

Charges ordinarily consist of a mixture of aluminum pig, scrap, remelted scrap, pure metals, and rich alloys of other metals with aluminum; but previously prepared or purchased ingot of the proper composition may be used to avoid the necessity for close attention to composition.

When alloying is done, metals with low melting points—such as magnesium, zinc, lead, bismuth and tin—are commonly added directly to the molten aluminum and stirred in. Magnesium is submerged below the surface of the molten aluminum to prevent burning. Such metals as manganese, iron, nickel, titanium and chromium dissolve so slowly that they are introduced as rich alloys or hardeners, normally containing from 2 to 10% of the metal in aluminum. Copper and silicon may be introduced directly, but their solution is moderately slow; consequently, rich alloys are frequently used.

Scrap may be added directly to the furnace charges, or previous melting and casting as small ingot may be desirable because of size, shape, cleanliness or doubtful chemical composition.

The composition of the completely molten bath is made uniform by manual stirring, which must be thorough, yet with the least possible disturbance of the surface oxide. The amount of oxide or skim that is formed will vary with the alloy and with the components used in the charge. If this oxide cover becomes very thick, it should be skimmed off. It should also be pushed aside from the area where metal is to be charged or ladled.

The metal bath may be fluxed with chlorine or aluminum chloride to float particles of oxide to the surface. Chlorine, as well as inert gases such as nitrogen and helium, will remove dissolved gas. A third use of chlorine and aluminum chloride, as well as salt fluxes of various chloride and fluoride mixtures, is to dry up the surface dross so that less entrapped metal will be removed during skimming.

It is unfortunate that variations in metal temperature and in soaking time have opposite effects on the two major melting problems of cleanliness and dissolved gas. Increases in bath temperature and in length of time held at temperature are beneficial from the standpoint of cleanliness, since nonmetallic inclusions are thus given a better opportunity to rise to the surface or sink to the bottom. However, the solution of gases, principally hydrogen formed by reaction with the bath of water vapor carried into the furnace by air and combustion gases, increases with metal temperature and time at temperature. The practice that is adopted will depend on many factors, including equipment, moisture content of the gases in the furnace, condition of the metal charged, fabricating difficulties, and requirements of the product. Since high temperatures also result in higher losses through oxidation and tend to coarsen the grain structures of the ingot, the practice generally preferred is to use metal temperatures as low as 1300 to 1400 F and to rely on fluxing, careful handling of the metal, and a final short soaking to give proper metal cleanliness.

Furnaces must be drained and cleaned periodically, and iron pots and tools must be coated with a protective wash. The walls and hearths of refractory furnaces are scraped to avoid excessive build-up of various deposits.

Casting. A poor product can be made from a good ingot, but a good product cannot be made from a poor ingot. Satisfactory ingot stock is essential for success in any metal working operation.

With an available supply of metal of the desired composition and metallurgical quality, a casting method must be used that will produce ingots of proper size, structure and surface quality. Ingot shape, cross-sectional area and length vary greatly; for instance, from short 4 by 4-in. wire bars and from 2 by 12-in. sheet ingots to ingots 20 in. thick, 48 in. wide and 8 ft long or more. Square cross sections are most common for ingots that are to be rolled into rod and bar, and rectangular shapes with high ratios of width to thickness, for sheet rolling. Round ingots are required for extrusion and some forging and pressing uses, and hollow round ingots for extrusion of tubing. These wide variations in size and shape greatly influence casting problems and the selection of the method to be used.

A study of ingot structures must include the subjects of crystal size and shape, constituent structure, porosity, inclusions, and uniformity of composition throughout the ingot. A fine equiaxed crystal structure is preferred and may be secured by suitable melting and casting practices, or in some instances by the addition of a grain refiner, such as titanium. Porosity resulting from liberation of gas or from improper feeding of solidification shrinkage will result in the blistering of fabricated products in annealing or solution heat treatment, and also may cause both cracking during working and low mechanical properties in the product. Dross or refractory inclusions have similar effects and are particularly serious in machining or in drawing to fine wire. Nonuniform composition will result in low mechanical properties in areas low in alloying elements.

The quality of the surface of aluminum alloy ingots may be impaired by cold shuts caused by improper or very slow transfer of metal into the mold; by included dross resulting from agitation during pouring; and by liquation when liquid having a low melting point is exuded through the partially solidified ingot surfaces.

The two principal requirements for a successful casting process are (1) the introduction of the metal quietly and uniformly without the inclusion of dross and the formation of cold shuts, and (2) the withdrawal of heat from the ingot at a fast enough rate and in a proper direction to produce a structure that is satisfactory for the intended use. The many procedures that have been used for transferring metal and withdrawing heat cannot be discussed here, but a brief description of the two methods in most common use will show the application of these casting principles.

Tilt-Mold Ingots. Until recent years, the most important type of aluminum and aluminum alloy ingot was the tilt-mold ingot, still extensively used. A heavy cast-iron book mold (a mold with hinges at one vertical corner or side and having diagonally opposed clamping devices) is mounted on trunnions, so that it can be rotated at a closely controlled rate around a horizontal axis at one of the top

corners or faces. Pouring is started when the mold is raised nearly horizontal, and while the mold is being lowered to a vertical position, the metal is introduced from a crucible slowly and without turbulence.

It is possible to avoid agitation and inclusions of oxide film by using equipment designed and operated properly; and the combination of slow pouring and water cooling of the bottom portions of the mold makes freezing possible from bottom to top in order to insure proper feeding to the solidifying metal in the lower regions. These features are the only characteristics distinguishing the tilt-mold process from ingot-making processes generally used in the steel and copper industries.

In the casting of strong aluminum alloys, the tilt-mold ingot has the disadvantages of a coarse constituent structure, a tendency toward fine porosity, considerable inverse segregation with low content of alloying elements at the ingot center, and relatively poor hot working characteristics. Because of the deep pool of metal still remaining molten in the mold when pouring is completed, and because of the high solidification shrinkage of aluminum, it is necessary to add the metal slowly and carefully with hand ladles for a long period in order to prevent a deep head-end pipe. These disadvantages, which increase in importance with increases in ingot size and in amount of alloying elements, have resulted in limiting the applications of the process. At present the tilt-mold process is used only for pure aluminum and the simpler alloys in quite wide ranges of shapes and sizes, and for strong alloys in small sizes to be worked by extrusion.

Directly Chilled Continuous Ingots. Recently, extensive use has been made of processes whereby metal is continuously introduced into a short, thin water-cooled mold; a shell is frozen by withdrawal of heat through the mold; the shell is withdrawn from the mold at a constant rate; and solidification is completed by direct application of water below the mold. By the use of lowering rolls and saw, the process can be carried out continuously for long periods, or a lowering mechanism may be provided to give intermittent operation for the casting of individual ingots of the desired length. In the intermittent method it is common practice to cast simultaneously two or more ingots from a single source of metal supply and with the same lowering mechanism.

This process, with extremely rapid withdrawal of heat by the application of water directly to the ingot, gives rapid cooling through the freezing range and therefore a fine constituent structure. The shallow freezing zone results in better feeding of solidification shrinkage and in greatly decreased inverse segregation of alloying elements. Since the shallow pool of molten metal freezes with only slight head-end shrinkage, the heading operation can be eliminated.

Ingots made by this process have excellent hot working characteristics, but the surfaces are ordinarily heavily liquated and may contain shallow cold shuts. This frequently necessitates scalping either the ingot or the partially fabricated product. Another disadvantage of the process is that many alloys tend to crack during cooling, as a result of high residual stresses.

The Hot Working of Aluminum Alloys

By John H. Alden*

THERE are two principal objectives in the hot working of aluminum alloys. The first objective, applicable to cast ingots of various types, is to deform plastically the as-cast structure, thereby converting it to a wrought structure and thus making it more workable and more adaptable to subsequent hot or cold working operations. The second objective is to obtain increased plasticity by using elevated working temperatures, thus permitting the economical manufacture of intricate parts or thin sections some of which could not be made by cold working.

Preheating of Ingots. Hot working of cast ingots is preceded by suitable heating of the ingot. With the more complex alloys, it is desirable to remove the cored cast structure or to dissolve and disperse certain constituents, or to do both. This is accomplished by heating the cast ingots to an elevated temperature and soaking them at such a temperature for a suitable period. The ingots may be hot worked directly thereafter, or they may be cooled to room temperature and reheated to the hot working temperature. Table I shows typical preheating treatments for some aluminum alloy ingots.

Table I

Preheating Treatments for Aluminum Alloy Ingots

Alloy[a]	Ingot Metal Temperature	Soaking Time at Metal Temp
3S, 4S	950 to 975 F	4 to 6 hr
14S, 17S, 24S	900 to 950 F	4 to 12 hr
A 51S, 52S, 53S, 61S, 63S	900 to 950 F	0 to 8 hr

(a) Chemical compositions of these alloys are listed on page 793.

With pure aluminum and some alloys, when it is not necessary to effect constituent changes in the as-cast structure, the ingots are merely heated to the desired hot working temperature just before performing the work.

Sheet and Plate. Ingots for the manufacture of sheet and plate are ordinarily wide and long in relation to their thickness, and those used in newer mills weigh several thousand pounds. When ingots show liquation, other surface segregation or cold shuts, they are usually scalped prior to working. Sheet ingots of the less easily workable alloys may be hot rolled to some intermediate thickness before scalping. The checks, cracks and other surface imperfections are then removed and the ingots are reheated and further hot rolled to slabs.

Modern mills for the hot rolling of sheet ingots are generally 4-high, although 3-high and 2-high mills are used extensively in the industry. There are a few installations where the hot mill is equipped with vertical edging rolls to roll the ingot edges, but ordinarily the edges of sheet ingot are unsupported and therefore are susceptible to edge cracking, particularly in the harder alloys.

This hot rolling or breakdown operation produces slabs for subsequent hot continuous rolling or cold rolling. When the hot mill slabs are to be cold rolled, the usual practice is to roll them on the hot mill down to thicknesses of ¼ to ½ in. If, however, the slabs are to be continuously rolled subsequently, the hot mill operations are stopped at thicknesses of one inch or slightly less.

In producing slabs for making Alclad sheet, the cladding is accomplished in the hot rolling operation. Slabs of the cladding alloy are strapped to a scalped ingot of the core material and the assembly is heated for rolling. The straps are removed after the assembly is placed on the hot mill table, and hot rolling is then done in a manner similar to that used with nonclad sheet ingots.

High-speed 4-high hot continuous mills, similar to those employed in the steel industry, were installed in several aluminum sheet mills just prior to and during the war. Hot mill slabs slightly under 1 in. thick are rolled on these mills to thicknesses ranging from 0.080 to 0.200 in. After continuous rolling, the stock is coiled or is sheared to straight lengths.

Slabs produced by these practices in hot mills and slabs and coils from continuous mills are ready, after annealing, for subsequent cold rolling into sheet.

Rod, Bar, Wire and Rolled Shapes. In the production of aluminum rod, bar, wire and rolled shapes, modern practice

*Assistant Chief Metallurgist, Fabricating Division, Aluminum Company of America, Pittsburgh

involves preheating, as for sheet ingots, before breaking down the ingot on a blooming mill. Ingots as large as 20 by 20 in. in cross section are rolled on such mills.

Blooming mills used for aluminum are similar to those employed for steel* and are generally 2-high reversing mills of about 5000-hp capacity. Since hot steel is more plastic than aluminum at hot rolling temperatures, reductions employed on aluminum blooming mills are somewhat less than on steel, but the types of passes are similar. Roll surfaces are smoother than the cogged surfaces often used on steel.

Depending on the alloy and the particular type of ingot employed, the ingot is often scalped prior to hot rolling. If the ingot is rolled unscalped, the bloom is generally scalped or local defects are removed by suitable conditioning tools. Temperatures employed during blooming-mill operations are shown in Table II. After inspection, blooms are ready for further hot rolling into wire, rod, bar and rolled shapes, or are used as stock for hot forging operations.

In the manufacture of wire and smaller sizes of rods, the blooms are further rolled to suitable size on continuous mills or train mills. For wire, such hot rolling is generally continued until the rod material is ⅜ in. in diam, at which size the metal is coiled, annealed and stocked for subsequent drawing. For medium sizes of rod and bar, hot rolling is stopped at a size a little larger than the finished dimensions. The metal is then annealed and cold rolled or drawn to finish size. Larger sizes of rod and bar are hot rolled to finish size on train mills.

Structural shapes are hot rolled to finish size. Designs of roll passes are similar to those used on steel, but the lower plasticity of the aluminum necessitates more passes to produce a given section. The principal problem in rolling aluminum shapes is the attainment of proper lateral flow so that the extremes of the section are just filled. Overfilling causes fins and underfilling causes surface cracking along the edges. As a rule, structural shapes are furnished in the heat treated condition.

The metal is subjected to compression and receives a large amount of plastic deformation during the extrusion operation. Frequently recrystallization takes place during the process of extrusion, and many sections emerge from the die at temperatures above the recrystallization temperature; therefore, extrusion of some alloys may develop a coarse grain structure. In addition, the extruded section is highly fibrous in structure, parallel to the direction of extrusion. As a result, tensile properties of the product are often higher than those obtained on other hot worked products or on some cold worked products. The size of the particular section has a pronounced bearing on the properties, and in a complex section containing portions of varying thicknesses, the properties may vary widely.

Extrusion speeds vary from 1½ to several hundred feet per minute, depending on the alloy, the section being produced and the temperature conditions employed. The upper limit of speed is usually dictated by the surface quality or dimensional requirements.

In the extrusion of tube blooms, tool setups must be carefully controlled to avoid too much eccentricity in the bloom. After extrusion the blooms are sawed to the desired length, are annealed, and are then ready for cold drawing into seamless tubing.

Forging.* Hot hammer forging is used for the manufacture of many aluminum parts. Hammers employed are similar to those used on steel, the largest being 35,000 lb. The forging stock, either round or square, is cut to suitable length and then heated to proper forging temperature. In making hammer-forged parts, a liberal flash is generally allowed.

The use of press forging is increasing rapidly. In this type of forging, the deformation takes place somewhat more slowly. Since press forgings are ordinarily made to close tolerances, it is important that ■ slug of accurate size be used in order to obtain uniformity in the finished piece.

Forging techniques and die design for both types of forging are similar to those employed for steel and, for that matter, are also similar to brass forging. Compared with the common steels, aluminum alloys require about 30% more energy or power to form a given forging properly from a given size of slug. Hot forging temperatures are shown in Table II.

Table II. Typical Hot Working Temperatures for Aluminum Alloys

Alloy[a]	Sheet and Plate: Breakdown, deg Fahr	Sheet and Plate: Continuous Rolling, deg Fahr	Extrusion, deg Fahr	Blooming Mill Breakdown, deg Fahr	Hammer Forging, deg Fahr	Press Forging, deg Fahr
2S, 3S, 4S, 52S	750 to 925	300 to 850	750 to 900	750 to 850	680 to 840	680 to 840
14S, 17S, 24S	750 to 850	600 to 850	650 to 850	775 to 850	760 to 820	800 to 860
18S, 25S	.....	.....	.....	800 to 870	760 to 820	800 to 860
32S, A51S, 53S, 61S, 63S	750 to 850	700 to 900	700 to 900	800 to 890	800 to 860	820 to 880

(a) Chemical compositions of these alloys are listed on page 793.

Extrusions. The extrusion process is employed for producing a wide variety of sections, ranging from round rods to very complicated and diversified cross sections. This process is also employed for producing tube blooms for the manufacture of cold drawn seamless aluminum tubing. Extrusion presses in this country range as high as about 5500 tons in capacity, and reports have been received of 12,000-ton presses in Europe.

In the extrusion operation, the cast cylindrical ingot is heated to the desired temperature and delivered to the press. The extrusion cylinder is heated by electricity or gas to minimize the loss of heat from the ingot. The ram of the press is fitted with a dummy block somewhat smaller than the cylinder diameter. As the ingot is extruded, this clearance between the dummy block and the cylinder leaves in the cylinder some of the original ingot surface. Furthermore, a certain length of the ingot is left unextruded and this is removed before charging another ingot. Temperatures employed in the extrusion of aluminum alloys are shown in Table II.

Lubrication. The hot working of aluminum alloys requires more power than the hot working of steel. Also, the fact that aluminum does not scale necessitates the presence of a film of suitable lubricant between the aluminum surface and the rolls or other hot working tools. For most hot rolling operations, large volumes of a soluble oil emulsion are employed, serving the dual function of roll cooling and lubricating. For extrusion, no lubricant is needed, except on the surface of mandrels for the extrusion of hollow blooms. Such mandrels are usually lubricated with a suspension of graphite in light mineral oil. In hot forging operations various die lubricants are employed, including graphite suspensions, tallow, and other specialized kinds. They must be carefully selected, however, to avoid adhesion of the metal to the forging die.

* *See* "The Hot Mechanical Working of Steel", page 343.

* For discussion of the principles of forging, see articles on pages 36 to 41 in this Handbook.

The Cold Working of Aluminum Alloys

By John W. Hood*

COLD working, as covered in this discussion, is limited to those processes employed in the fabrication of the basic products—plate, sheet, foil, rod and bar, wire, tubing, and impact extrusions—in which the aluminum alloy is at approximately room temperature when the process begins. Hot working is employed for the breakdown or roughing operations, and in some instances even for the finishing operations. However, cold working is employed for various reasons in the fabrication of the foregoing basic products made of aluminum and aluminum alloy.

Purposes of Cold Working

In the cold working of all aluminum products one or more of the following objectives is attained:

Increase in Strength and Hardness at the Expense of Ductility. Aluminum and its alloys, like other metals, strain harden during cold working, especially at low temperatures. The increase in the tensile strength, based on the strength of the alloy in the annealed (or heat treated) temper, is directly proportional to the amount of cold work expressed as the fractional reduction of the initial cross-sectional area. This direct proportionality applies throughout most of the range normally used in commercial manufacturing operations. For higher reductions, the tensile strength increases more rapidly than would be indicated by this relationship.

The yield strength of annealed (or heat treated) material, that is, the stress which produces a permanent set of 0.2%, is increased rapidly by the first small amounts of cold work. Succeeding reductions produce relatively less effect until, after about 20% reduction in cross-sectional area, the rate of increase in this property parallels quite closely the increase in tensile strength.

The elongation decreases with increasing amounts of cold work and, as in the yield strength, the first small amount of cold work produces a relatively greater effect (in this instance, a decrease) than subsequent reductions of equal amount. The first reduction of 20% usually reduces the elongation to about ⅓ of its initial value or even less; after a reduction of about 60%, further cold working causes little additional change in this property.

This principle is utilized in the fabrication and control of tempers of the aluminum alloys that cannot be heat treated, as illustrated by the typical mechanical properties of 2S (99% Al min) listed in Table I.

The principle of strain hardening by cold work is employed also in the heat treated alloys (1) in flattening after solution heat treatment, and (2) in producing higher strengths than are available from heat treatment alone. The effect of cold work on the typical tensile properties of 24S sheet* $\frac{1}{16}$ in. thick, after solution heat treatment and aging at room temperature, is shown in Table II.

Refinement of Grain Structure. The amount of strain hardening or cold work in the metal prior to a heating operation is one of the important factors affecting the temperature of recrystallization and the grain size. In general, it is considered good practice to specify not less than approximately 50% reduction in cross-sectional area by cold working or its equivalent between annealing or heat treating operations, in order to prevent the development of excessively large grains. The amount of reduction required for obtaining a specific grain size varies with the composition of the alloy and many other factors beyond the scope of this article.

Straightening or Flattening. Straightening and flattening operations are employed normally for all tempers of aluminum alloys, except for the annealed temper or for material that is to be formed immediately after solution heat treatment. It is expected that maximum workability is required in these latter tempers and the normal forming operations to be imposed will preclude the necessity for straightening prior to forming.

Except for the extremely large sizes, straightening and flattening operations are performed cold and are usually controlled so as to introduce a minimum amount of strain hardening. However, some strain hardening may result, since straightening and flattening can be accomplished only by stressing the metal beyond the elastic range in order to produce permanent set.

In addition to hand bending and hammering, which represent the earliest forms of straightening and are still employed, other methods in general use involve equipment designed for straightening and flattening specific products.

Staggered roll levelers are employed for flattening sheet and plate. These devices bend the metal back and forth in successively decreasing amounts as it passes between the rolls. Contact of the sheet or plate with the driven rolls develops sufficient friction to hold the metal in tension.

Roll straighteners that act on the metal by a combination of flexing, rolling and stretching are also in common use for straightening rod and tubing. The rolls are located at angles that cause the rod or tubing to rotate. Flexing is accomplished by the position and shape of the driven rolls. The gripping of the metal in the rotating rolls causes it to flow circumferentially; therefore this action is employed also to shape and size the metal.

Stretchers are in general use for straightening and flattening sheets, tubing, rod, bar and wire. Tensile stresses

Table II. Effect of Cold Work on 24S-T4 Sheet

Designated Temper	Yield Strength, psi	Tensile Strength, psi	Elongation, per cent in 2 in.
24S-T4[a]	44,000	67,000	21
24S-T3[b]	46,000	68,000	19
24S-T36[c]	57,000	73,000	13

(a) Solution heat treated, aged at room temperature, not flattened
(b) Solution heat treated, aged at room temperature, flattened by combination roll and stretcher leveling
(c) Solution heat treated, aged at room temperature, cold rolled sufficiently to reduce thickness approximately 6%

(b) These reductions vary widely with alloy composition, type of product and method of fabrication, and should be considered only as illustrative of relative orders of magnitude.

are applied through suitable jaws attached to each end of the metal. Machines for stretching are normally operated by hydraulic power so that the load may be applied gradually and may be controlled properly as the metal is elongated. Because of the marks remaining from the gripping of the jaws, it is necessary to remove the ends of the stretched pieces after stretching. Together with the time required for loading and unloading, the removal of ends may make this method of straightening more costly than roll flattening and straightening.

Increase in the Accuracy of Dimensions. Some products, particularly plate, rod and bar, are hot worked nearly to the finish dimensions and are then cold finished to obtain greater accuracy of dimensions.

Improvement in Surface Appearance. In the fabrication of certain products, such as sheet, tubing, bar and rod, bright finishes are attained as a result of the proper choice of lubricant, tool or roll shape and surface, together with the burnishing effect obtained by cold reduction. In general, the brighter surfaces are obtained in the harder tempers and with the greater reductions, provided lubrication is ample to prevent discoloration caused by overheating or by adhesion of the metal to the tools.

Control of Characteristics of Metal Flow During Subsequent Forming Operations. The tendency of sheet metal to draw "ears" or to develop a scalloped edge during a cylindrical drawing operation is caused by preferred orientation of grains. Metal that has random grain orientation draws symmetrically with an edge of uniform height from the base of the drawn shell. Random orientation of grains is obtained in the process of fabrication, by the proper balance of recrystallization and cold work. For this reason the amount of reduction by cold work between annealing operations is often an important factor in the successful use of sheet.

Certain alloys exhibit a tendency to develop "Lüder's lines" or flow lines on the surface when stretched. Such a tendency is pronounced in the annealed temper. The introduction of slight amounts of strain hardening by compressive cold work will minimize the tendencies during subsequent stretching operations. This compressive cold work may be introduced by roll leveling, cold rolling or by other methods, and the resistance to the development of Lüder's lines is roughly proportional to the amount of strain hardening thus introduced.

Cold Worked Products

Dimensional ranges and notes on the cold working of specific products are given here.

Plate. By definition, plate is material ¼ in. or more in thickness. This product is usually rolled hot to gage but may be finish rolled cold, particularly for plate less than ½ in. thick, or for the intermediate tempers of the alloys that cannot be heat treated. In the "as-rolled" temper of the alloys that cannot be heat treated, the mechanical properties may vary widely because such a temper may be finish rolled either hot or cold.

Sheet. By definition, sheet is material within the range of thickness from 0.005 in. to and including 0.249 in. The cold rolling methods employed for sheet are divided into two general classifications; namely, the flat roll and the strip roll methods.

In flat rolling, the sheets are handled in relatively short lengths and remain flat. In the lighter gages, that is, approximately 0.040 in. or less, the sheets are finish rolled in packs of two or more.

In strip rolling, the sheets remain in relatively long lengths and are wound in coils between successive passes in order to facilitate handling and application of tension. The sheet is guided into the rolls and kept reasonably flat as a result of suitable tension applied by steel bar "bridles" equipped with guides, or by brakes applied to the unwind reel. Upon emerging from the rolls, the sheet is coiled on a reel or by means of a 3-roll coiler for heavier thicknesses.

Because the flatness of the sheet is controlled by means of tension provided in strip rolling, much greater reductions per pass are possible than in flat rolling. It is the normal practice to make the largest reductions on the first pass after annealing and to use progressively smaller reductions for subsequent passes.

The greater amount of work per pass introduced by the strip rolling operation entails the use of more lubrication than in flat rolling. Therefore the surfaces of strip-rolled products supplied in the as-rolled or intermediate tempers are normally oily, whereas flat rolled products are relatively free from oil.

Various finishes are applied to aluminum sheet products, ranging from bright to dull, as determined by the intended use. The finish produced is determined by the type of grind applied to the rolls and is influenced also to a considerable degree by the control of auxiliary equipment, lubrication, roll temperatures and annealing methods.

Foil. By definition, foil is material not more than 0.005 in. thick, and is available commercially as thin as 0.00025 in.

Foil rolling is a continuation of the rolling methods for strip sheet to thicknesses 0.005 in. or less. Because of the more fragile nature of the metal in the foil thicknesses, control of tension, lubrication and roll shapes must necessarily be more accurate than for the heavier gages of sheet.

The thickness of foil is controlled by adjusting the speed of the rolls rather than by varying the roll opening. In finishing to thicknessess less than approximately 0.001 in., it is customary to finish roll in packs of two sheets engaged in the rolls at the same time. This accounts for the variation in the luster on the two sides of the lighter gages of foil. The thickness of foil is measured by weighing a sample of known area on a carefully calibrated balance. It is common practice to express the thickness in terms of covering area, as square inches per pound as well as in thousandths of an inch.

Rod and Bar. These are defined as products falling within the following approximate size limitations: rod, ⅜ to 3 in. in diam, inclusive; rectangular bar, 0.081 to 1½ in. thick, inclusive, 4 in. wide max; hexagonal bar, ⅜ to ■ in. inclusive, distance across the flat surfaces.

Rod and bar are normally produced by hot rolling to final dimensions, although where better surface finish and closer dimensional tolerances are required, the final reductions are made cold. These products are specified as rod and bar, cold finished. The cold reductions may be made by drawing through dies, cold rolling, roll straightening or combinations of these processes, depending on the finished sizes, the results required, and economical considerations.

Wire. Supplied in various forms, wire is defined within the following approximate size limitations: diameters, 0.005 to 0.374 in. inclusive; wire-flattened, 0.010 to 0.187 in. thick, 0.030 to ■ in. wide; wire-flattened and slit, 0.010 to 0.080 in. thick, 0.125 to 4.75 in. wide.

Wire is drawn from larger sizes of rod to the desired dimensions by successive cold reductions through dies made of chilled cast iron, tungsten carbide, diamond, or through "Turk's-head" dies. "Flattened" and "flattened and slit" wire are produced, as the names imply, by rolling a round wire flat, and slitting the flattened wire to the required width. Flat sections with round or square edges can be produced by this method.

Tubing. This form is manufactured in sizes ranging from approximately ⅛ to 12 in., outside diameter, and with wall thickness from 0.010 to ½ in., depending on the outside diameter.

Tubing is manufactured by bench drawing or otherwise reducing from extruded blooms to the required finished dimensions. The drawing process consists essentially of pulling the tube through a hole in a die, thus reducing the outside diameter, while a mandrel inside the tube controls the inside diameter.

Another tube-reducing process employs dies with tapered grooves. These dies are rocked back and forth over the tube, compressing the metal of the tube against a mandrel which governs the inside diameter. The tube is fed through the dies intermittently and is rotated, so as to distribute the working action over the entire circumference of the tube.

The process is determined by the finished size of

tube, the type of finish and the accuracy of dimensions required.

Impact Extrusions.* These are manufactured commercially within the following approximate size limitations: diameter or distance across flats, ¾ to 5 in. inclusive; minimum bottom thickness, 0.020 to 0.075 in. inclusive; minimum wall thickness, 0.010 to 0.281 in. inclusive; maximum length, 4½ to 10 in. inclusive. The limits of any one dimension are determined by the alloy and the other dimensions.

Impact extrusions are cup-shaped objects produced by striking a high-speed impact blow with a punch into a die cavity containing a cold slug of metal, approximately the shape and size of the outer cross-sectional dimension of the shell. The die cavity is of the same size and shape as the outside of the desired part, and the punch is of the same size and shape as the inside of the part to be produced. The impact is sufficient to cause the metal to fill the die cavity and to flow or squirt upward out of the die and around the punch. Speed is the important characteristic of this method of cold working. The movement of metal takes place in a fraction of a second. Collapsible tubes, commonly used as containers for toothpaste, shaving cream and similar commodities, are examples of products made by this process.

*For a description of the process of impact extrusion, see the article "Extrusion of Lead and Lead Alloys", page 947.

The Forming of Aluminum Alloys

By L. J. Weber*

ALUMINUM is one of the most workable of the common metals. The principles of forming all metals are basically the same, but for each metal there is a difference in the amount of permissible deformation, the details of tool design, annealing procedures and such. The data and procedures discussed here are those which have been found most satisfactory in commercial practice.

General Sheet Metal Practice for Aluminum. Forming operations, such as bending, rolling, flanging, beading, curling, crimping and hammering, can be classified under general fabrication of sheet metal. Bending is the basic operation in most sheet metal work. During bending, the metal on the outside of the bend is stretched while that on the inside is compressed. If breaking occurs or if the metal is severely strained during or after the forming operation, a larger bend radius should be used, or the alloy or temper should be changed to provide material with better bending characteristics. Tables I and II show bend radii for the different aluminum alloys and tempers that have been used successfully with a variety of types of forming equipment. These tables should be used only as a guide to determine the approximate radius for each specific job.

Bending may be done on the ordinary folding brake or bar folder, using approximately the same technique as for other metals. The power brake with the proper tooling will produce a variety of shapes. The tools that are used most widely are V-dies with punches that have suitable radii. For relatively thin metal, a block of rubber retained in a steel channel section may be used as the die. As the sheet is forced into the rubber, the metal assumes the shape of the punch, which is designed with the proper radii for obtaining the desired contour.

Edging, beading or curling rolls are often employed to produce a beaded or half-round edge. The rolls employed are usually specifically designed to meet the requirements of the job. Many complicated shapes can be formed by utilizing roll molding machines where the material travels through successive rolling operations in a single machine.

Curved surfaces or cylinders may be fabricated by roll forming. In the production of cylinders by this method, an area remains flat, approximately equivalent to the distance between the lower front and the back roll. This flat area may be minimized by preforming the ends of the sheet to the proper radius before the sheet is fed into the forming rolls.

The Drawing of Aluminum. Aluminum is drawn on the same type of equipment that is used for other metals. Many shallow draws are made on single-action presses because of the high speed at which such presses can be operated. If no blank-holder is used in the drawing operation, the metal must be thick enough to avoid wrinkling. With thin metal, a blank-holder is usually required, and an air cushion is sometimes attached to the press, or springs are built into the tools to provide the necessary pressure against the blank-holder to avoid wrinkling.

Deeper draws require the double-action press, which has an outer ram where a blank-holder is attached and an inner ram where the punch is attached. When a shell is being drawn, the outer ram, with the blank-holder attached, descends first and exerts pressure on the outer edge of the blank; the inner ram, to which the punch is attached, then descends and forces the metal into the die. The pressure on the blank-holder must be adjusted to permit the blank to slip and, at the same time, prevent the formation of wrinkles. If the blank is held too tightly it will break. To obtain a smooth shell of metal that is uniform in thickness it is always necessary to adjust the pressure on the blank-holder with care.

The proper temper of the common aluminum alloys is determined by the article to be drawn. For severe draws, annealed sheet is used, but for less severe draws, the intermediate tempers or even full hard temper may be used.

Heat Treatable Alloys. When heat treatable alloys are required, severe draws are usually made from annealed sheet. For less severe draws, the sheet may be given the solution heat treatment, and the aging may be retarded by keeping the sheet at a low temperature (minus 20 F will virtually prevent aging in most alloys) until the drawing operation is performed. Very shallow shapes may some-

Table I. Bend Classification for Making a 90-Deg Cold Bend in Aluminum and Aluminum Alloy Sheet

The minimum permissible radius varies with the nature of the forming operation, the type of forming equipment, and design and condition of tools. The minimum working radius for a given material, or hardest alloy and temper for a given radius, can be ascertained only by actual trial under the contemplated conditions of fabrication.

Alloy and Temper(e)	Bend Classification(a)	Alloy and Temper(e)	Bend Classification(a)
2S-O	A	24S-O(b)	B
2S-H12	B	24S-T4(b)(c)	J

D	0	0	0 to 1t	½t to 1½t	1t to 2t	1½t to 3t
E	0 to 1t	0 to 1t	½t to 1½t	1t to 2t	1½t to 3t	2t to 4t
F	0 to 1t	½t to 1½t	1t to 2t	1½t to 3t	2t to 4t	2t to 4t
G	½t to 1½t	1t to 2t	1½t to 3t	2t to 4t	3t to 5t	4t to 6t
H	1t to 2t	1½t to 3t	2t to 4t	3t to 5t	4t to 6t	4t to 6t
J	1½t to 3t	2t to 4t	3t to 5t	4t to 6t	4t to 6t	5t to 7t
K	2t to 4t	3t to 5t	4t to 6t	5t to 7t	5t to 7t	6t to 10t

times be formed in the full heat treated *T* temper, but difficulties are often encountered because of breakage caused by the high strength of the alloy and the comparatively low elongation.

Alloys that develop their maximum properties by aging at an elevated temperature are frequently drawn in the as-quenched or *W* temper. The time that elapses between the solution heat treatment and drawing should be kept at a minimum since these alloys do harden to some extent at room temperature. The desired strength is then obtained by heating the formed parts to the proper aging temperature for the necessary period.

Successive Reductions. Long experience has indicated that the successive reductions given in Table III are nearly optimum for drawing cylindrical shells. Tools designed to give these reductions will usually operate satisfactorily. Although higher reductions may be used occasionally, great care should be taken to avoid making the draws too critical, because otherwise the loss in scrap, as well as the loss of time in production, will quickly exceed the expense saved in tooling.

Table III. Reduction in Diameter for Deep Shells

Operation	Suggested Reduction
Blank ..... (D)	.....
First draw ..... (D_1)	0.40D
Second draw ..... (D_2)	$0.20D_1$
Third draw ..... (D_3)	$0.15D_2$
Fourth draw ..... (D_4)	$0.15D_3$

Apparently the best results are obtained when the radius of the die is no less than four times and no more than fifteen times the original thickness of the metal. The radius of the punch should be at least four times the thickness of the sheet. If the radius is too sharp, the resistance to the flow of metal may cause fractures. If the radius is too large, wrinkling may occur in the sidewall of the shell.

Usually the drawing tools are designed so that the original thickness of the sheet is changed very little. This practice differs from that for brass and steel, which may be reduced in thickness as much as 50%. For this reason, it is often necessary to rework tools designed for brass and steel, when these tools are to be used to draw aluminum alloys.

Dimensions of Dies. In rectangular shapes, the greatest flow of metal occurs at the corners and must be controlled to prevent wrinkles and fractures. Provisions for this flow can be made by varying the radius of the draw. Ideally, the dimensions of the original blank should be such that there is just enough metal to obtain the desired shell. Care used in developing the blank often means the difference between success and failure in drawing. The suggested dimensions of dies for drawing rectangular and cylindrical shapes are given in Tables IV and V respectively.

Lubricants. A lubricant for drawing has two important functions: (1) it allows the blank to slip readily between the blank-holder and die; (2) it prevents galling and scratching while the movement takes place. Mineral oils or compounded mineral oils are most often used. Water-soluble drawing compounds have been tried but have been found less satisfactory. Some of the oils that have proved suitable in production operation are the following:

Light draws .....Light lubricating oil
Medium draws .....Mixture of light and heavy lubricating oil
Severe draws .....Heavy lubricating oil or a mixture of 50% mutton tallow and 50% paraffin
Very severe draws....Mixture of 30% mutton tallow and 70% paraffin

It should be remembered that the proper choice of lubricant for a particular plant is a matter of experience and depends on factors such as tool design, tool materials and sheet thickness.

The Stretch Forming of Aluminum. The use of stretcher presses for forming parts has increased considerably during the past few years. In this operation the edges of the sheet are clamped tightly; then a punch of desired shape is pushed up against the sheet by means of a hydraulic ram. The metal is actually stretched over the punch and thus takes the required shape. This method of forming can be used for making long, sweeping contours where sharp radii are not used.

Molding and extrusions can also be formed by this method. The ends are not clamped fixedly as with sheet but instead are clamped in jaws attached to air cylinders or hydraulic cylinders. A variation in pressure can be applied on these cylinders to obtain a part that is satisfactory in shape without causing wrinkles.

The Forming of Aluminum by Means of a Drop Hammer. Drop hammers are especially suitable for small production runs, since the dies and punches are usually made from soft alloys and are therefore both cheap and easy to produce. The parts that are made on drop hammers are usually shallow and have liberal radii.

Table IV

Dimensions of Dies for Drawing Rectangular Shapes

First draw .....Add 2.2 times blank thickness to punch dimension
Second draw .....Add 2.2 times blank thickness to punch dimension
Final draw .....Add 2.0 times blank thickness to punch dimension

Table V

Dimensions of Dies for Drawing Cylindrical Shapes

First draw .....Punch diameter plus 2.2 times thickness of blank
Second draw .....Punch diameter plus 2.3 times thickness of blank
Third and succeeding draws .....Punch diameter plus 2.4 times thickness of blank
Final draw of tapered shells .....Punch diameter plus 2.0 times thickness of blank

Guerin Process. Forming with rubber, also commonly known as the Guerin Process, is a procedure that was employed frequently for forming airplane parts during the war. The tool setup is usually inexpensive and a number of parts can be formed at one time. This process is especially useful in flanging and forming shallow parts.

Bending Tubes and Shapes. In the bending of tubing or shapes, the material on the outside of the bend is stretched and that on the inside is compressed. Therefore the metal must be ductile enough to permit both stretching and compression to take place.

The size and shape of the tubing also govern the bends

that can be made. The sharpness of bend depends on the diameter of the tubing and on the ratio of wall thickness to diameter. The thinner the wall of the tubing, the more tendency there is for rupture on the outside of the bend. Extremely thin-walled tubing has a tendency to fail by buckling on the inside of the bend. Besides fracturing and buckling, another difficulty that must be overcome in this bending is the tendency of the tubing to flatten or distort at the point of the bend. The curves in Fig. I give bend radii that can be used as a guide for forming aluminum tubing.

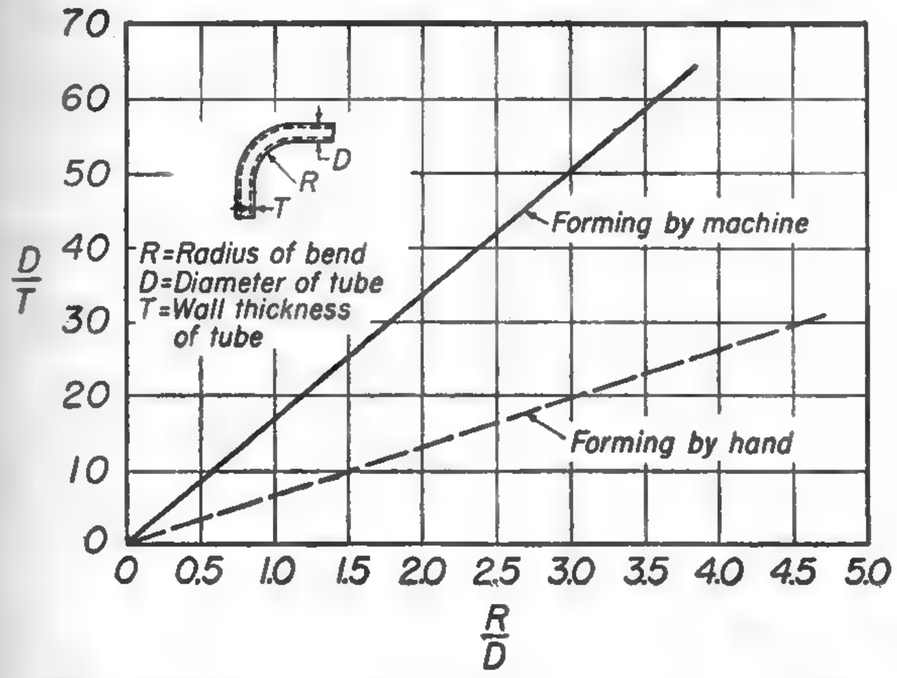

Fig. 1 Suitable bend radii for round aluminum alloy tubing (alloys 2S-H14, 3S-H14, 61S-T4, 52S-H32, 24S-O)

The essential parts of mechanically operated machines for bending tubes and shapes are the hub, follow block, clamp and mandrel. The tube is slipped over the mandrel (which is mounted on a rod that is long enough to accommodate various lengths of tubing) and is placed between the follow block and the hub, both grooved to fit the tube. The clamp blocks then hold the tube against the hub in order to make the bend when the hub is rotated. The mandrel supports the inside of the tube during bending, and must be located so that its point of curvature is exactly even with the center line of the hub. If the mandrel is ahead of this point, the tube will break; if the mandrel is too far back, the tube will flatten. Since the tube must slide against the blocks as it is being bent, lubrication must be provided.

The Heat Treatment of Aluminum Alloys

By C. F. Nagel, Jr.,* P. V. Faragher* and W. E. Sicha*

SINCE the data sheets concerning the individual aluminum alloys give the temperature ranges for heat treatment and the physical properties thus obtained, this article will discuss the heat treatment processes and the general principles involved.

Heat treatment improves the mechanical properties of several wrought or cast aluminum alloys. At least the principal hardening constituents in all these alloys are substances that have distinctly higher solid solubility in aluminum at elevated temperatures than at room temperatures. Heat treatment is simply a means of distributing the alloying ingredients more efficiently so that they can perform more effectively their function of hardening the metal.

Aluminum alloys that are susceptible to heat treatment solidify too rapidly in the production of castings and ingots to permit attainment of equilibrium conditions. The dendrites formed during early stages of solidification consist of solid solution, which varies in composition from the core to the outer layer of the dendrite arms.[1] An appreciable percentage of the added hardening elements is present in the form of eutectic or relatively large particles of a rich alloy. These conditions exist in spite of the fact that the total amount of the hardening elements may be completely soluble in solid aluminum at temperatures just below the melting point, for equilibrium conditions.

Working of the aluminum alloy ingots tends to break up the cast structure and thereby increase the rate of solution of the soluble alloying constituents when the metal is subsequently heated. Also, solution is more rapid in castings with a small grain size and fine dendritic structure. In general the heat treating temperature is made as high as possible without melting any of the eutectic material that is present in a particular alloy. The alloy is held at the high temperature long enough for solution and diffusion to take place and produce, as nearly as practicable, a homogeneous solid solution. The alloy is then rapidly cooled or quenched so that there is not time for the hardening elements to precipitate from solid solution during the cooling period, in accordance with their lower solubility at lower temperatures. This process is called "solution heat treatment". Such treatment increases all the mechanical properties.

* Metallurgical Department, Aluminum Company of America, Pittsburgh
* Aluminum Research Laboratories, Aluminum Company of America, Cleveland

Following solution heat treatment, the dissolved alloying constituents tend to precipitate from solid solution in accordance with their true solubility relations at room temperature and to coalesce into larger particles. The rate of this precipitation varies both with the alloy and with the temperature. Even with 24 S (4.5% Cu, 1.5% Mg, 0.6% Mn, remainder Al), which ages rapidly at room temperatures, holding at subzero temperatures suppresses the precipitation almost indefinitely. When the material is brought back to room temperature, age hardening proceeds at the normal rate. In contrast, 25 S (4.5% Cu, 0.8% Mn, 0.8% Si, remainder Al) ages very slowly at room temperature and must be held at slightly elevated temperatures to bring about any substantial change in mechanical properties. Other wrought alloys show appreciable increases in properties after aging at room temperature, and they reach a substantially stable condition in most instances within a matter of days; but if subjected to an artificial aging treatment, they show a marked further increase in yield strength together with some increase in tensile strength.

The aging that occurs at room temperature in solution heat treated casting alloys is usually most marked in the first few days after quenching and proceeds at a slower rate over a period of several weeks. This aging is substantially completed in three months or less in most casting alloys. Precipitation is greatly accelerated by aging at slightly elevated temperatures. Aging generally increases the tensile and yield strengths and hardness but reduces the ductility.

It should be noted that during aging or "age hardening" at room temperatures, or artificial aging (commonly called "precipitation heat treatment") at slightly elevated temperatures, even the larger particles formed are usually too small to be resolved by the optical microscope. By prolonged heating it is possible, in all solution heat treated aluminum alloys, to enlarge the precipitate to a size visible under the microscope. Particles of the size that results from aging treatments are more effective in hardening the metal than are the atoms of alloying constituents that are present in solid solution, and these particles are also more effective than the larger particles that result from prolonged heating or "overaging".

The foregoing paragraph outlines the theory presented by Merica and his associates to explain the facts observed in the heat treatment of aluminum alloys. This theory may not describe completely the phenomena that occur, but with the slip interference theory of Jeffries and Archer,

which pictures the particles as keying the crystal planes against slip, it gives a mechanical analogy that is easy to remember and explains the nomenclature in common use for these processes.

Thermal Treatment Processes. Three basic types of thermal treating processes are commonly applied to aluminum alloys:

1 Solution heat treatment consists in heating the alloy to a temperature at which certain constituents go into solution, usually in the range from 900 to 1000 F, and then quenching the metal to maintain these constituents in solution during the period of cooling.

2 Precipitation heat treatment consists in heating the alloy at a slightly elevated temperature, usually in the range from 250 to 400 F, to accelerate precipitation and agglomeration of the constituents in supersaturated solid solution.

(*a*) Such a precipitation treatment usually follows solution treatment.
(*b*) A precipitation treatment may be applied to material that has not received solution heat treatment. Certain fabricating processes for wrought alloys hold hardening constituents in solid solution in concentrations appreciably greater than the equilibrium solubility at room temperature. Similarly, the cooling rates that prevail in the production of commercial castings retain a degree of supersaturation of the solid solution at room temperature.
(*c*) Casting alloys that have received solution heat treatment may be overaged by application of a precipitation treatment at a temperature somewhat higher than the temperature range noted above. Overaging results in precipitation in excess of that which imparts maximum hardness and strength.

3 Annealing consists in heating to a temperature intermediate between the solution and precipitation heat treating temperatures to attain essentially complete precipitation and to remove residual strains.

Thermal Treating Practice.* *Furnaces for Solution Heat Treatment.* Wrought aluminum alloys are commonly heat treated in molten salt baths or in air furnaces, but the casting alloys are almost invariably heat treated in air furnaces. The salt bath consists either of fused sodium nitrate or, if the bath is also to be used for annealing, a mixture of equal parts of sodium and potassium nitrates. Provision should be made for the proper circulation of the bath throughout the immersed load of metal, to insure uniform temperatures in all parts of the bath. Gas, oil or electricity may be used to heat the bath, which is held in a steel or cast-iron tank.

By far the largest tonnage of aluminum alloys is heat treated in air furnaces, which may be heated electrically or by gas, oil or radiant tubes; the type of heating selected usually depends on local conditions. For best results artificial circulation should be provided. Furnaces in which products of combustion are circulated can be used satisfactorily if the atmosphere contains a sufficiently high percentage of carbon dioxide and is free from sulfur compounds and excessive moisture.[2] If electrical heating is used, the units should be of the type that has a low input of energy per unit of area. The baffles used to direct the air circulation may also serve to minimize direct radiation to the charge.

Furnaces for Precipitation Heat Treatment. Precipitation heat treatment is carried out in a furnace or oven usually heated electrically or by gas. Provision should be made for circulating the air in order to obtain a uniform temperature throughout the furnace, as well as more rapid transfer of heat.

Furnaces for Annealing. Furnaces for annealing are heated ordinarily by oil or gas but electric furnaces are also used. The permissible temperature range for annealing is wider than for solution or precipitation heat treatment.

Pyrometric Equipment. Since accurate temperature control is essential for best results, all pyrometers should be calibrated at regular and frequent intervals. Automatic temperature recorders are desirable, if not essential, to provide a record of the heating period, as a means of insuring that the material has been heated for the required time within the desired temperature range and that it has not been overheated. Furnace operation is simplified by equipment that regulates the temperature automatically, but manual control is possible. For further information about pyrometry see the article on page 174.

Solution Heat Treatment. Aluminum alloys in large tonnage are heat treated successfully without difficulty. Therefore, the following detailed instructions and precautions should not be interpreted to mean that proper heat treatment is a difficult process that cannot be carried out under commercial conditions. Proper practices are necessary for satisfactory results, but with ordinary care the required methods are established readily on a normal operating basis.

The temperature of the salt bath or of the furnace should not be higher at any time during the period of heat treatment than the maximum temperature specified for heat treatment of the alloy. This maximum temperature is chosen so as to be as high as possible without exceeding the melting point of the eutectic that is present in the alloy. If this eutectic is melted during heat treatment, the mechanical properties and usually the surface appearance of the alloy are seriously injured.

If the alloy is not heated to the minimum temperature specified, the full mechanical properties will not be developed and, in some instances, the resistance to corrosion of the resulting product will be below standard.

It is not possible to obtain satisfactory results by heat treating different parts of a piece of metal in succession. A piece must be uniformly heated throughout and quenched in all parts in the same operation.

The heating time is measured from the time the coldest part of the load reaches the minimum of the temperature range for heat treatment as determined from a temperature survey of a production load. The time at temperature will vary with the nature of the product and the alloy. Thick massive sections of wrought alloys require heating periods as long as a few hours; for thin sheet a few minutes may be sufficient. Relatively long heating periods are required for solution heat treatment of casting alloys.[1] The actual periods of time required will be determined from experience in operating the equipment with the various types of material to be heat treated. The consistent development of satisfactory mechanical properties is the criterion of correct heat treatment.

For clad wrought alloy products, the minimum possible time should be used in order to avoid the diffusion of the alloying constituents of the core through to the surface.[3] Since different thicknesses of metal require different times of heating, it is preferable not to heat treat clad products of very different thickness in the same load.

Quenching. After the alloy has been heated for the required time, it is removed and quenched. The time interval should be as short as possible between the removal of the load from the heating bath or furnace and the complete immersion of the metal in the quenching medium; in any event the interval should not exceed a few seconds for wrought alloys. Particularly for thin material, the use of guard sheets will minimize the loss of heat during the period of transfer. In quenching castings commercially, a time interval of considerably less than one minute can be realized between removal from the furnace and immersion in the quenching medium.

Allowing the metal to cool in the air is equivalent to quenching from a lower heat treatment temperature, and both mechanical properties and resistance to corrosion may be impaired. Quenching wrought alloys in hot water, in oil, or in air, may develop the required mechanical properties, but the resistance to corrosion is usually inferior to that of material quenched in cold water. However, in some instances, such practice may be necessary to avoid warping. Relatively slow cooling from the solution treatment may be permissible for forgings made of 53 S (0.7% Si, 1.25% Mg, 0.25% Cr, remainder Al) and 14 S (4.4% Cu, 0.8% Si, 0.75% Mn, 0.35% Mg, remainder Al), since the resistance to corrosion of these materials seems to be influenced less by cooling rate than that of some of the other heat treated wrought alloys. The quenching rate does not ordinarily influence the resistance to corrosion of aluminum casting alloys, but relatively rapid quenching in boiling water contributes to maintenance of the desired mechanical properties.

If the metal has been heated in a nitrate bath, it must

* For general information concerning furnaces and salt baths, see the articles on pages 267 to 283.

be thoroughly washed to remove the salt completely, since otherwise nitrate may initiate corrosion of the metal. For this purpose, warm water (150 F) may be used after the metal has been quenched in cold water, because of the greater solubility and higher rate of solution of the salt at higher temperatures.

Precipitation Heat Treatment. The rate of precipitation from supersaturated solid solution and agglomeration into larger particles varies for different alloys and also depends on the temperature. If the temperature of the material is raised moderately after quenching, the rate of precipitation is increased. Moreover, with proper choice of temperature, the resulting tensile and yield strengths are very much higher than those developed by room temperature aging, and the elongation is appreciably lower. Also the increase in yield strength is substantially greater than the increase in tensile strength.

The first effect of aging at elevated temperatures is a small loss in tensile and yield strengths but, as the process is continued, these properties increase, pass through a maximum and then decrease to values intermediate between those of the "as-quenched" and annealed conditions. The elongation decreases at first quite rapidly, then more slowly to a constant value. The time required to reach the maximum strength decreases as the aging temperature is raised, but the value for the maximum strength also decreases. At still higher aging temperatures the strength decreases continuously from the start.

For precipitation heat treatment in industry, the temperature must be high enough to permit development of the desired properties within a reasonable time, from the standpoint of economy and efficiency of plant operation, but not high enough to result in too great a sacrifice in the properties that can be obtained in the alloy. Also the aging period must not be so short that variations such as result from differences in time required for all parts of the load to come to temperature, cause appreciable variation in the properties that are obtained.

In general, the properties are the same whether the precipitation heat treatment is begun immediately after quenching or after aging at room temperature for any period of time. There is some evidence that there may be a small improvement in the properties of 75 S (5.5% Zn, 2.5% Mg, 1.5% Cu, 0.3% Cr, 0.2% Mn) if artificial aging is not begun during the interval between 2 hr and 2 days after quenching, but the improvement is not sufficient to complicate production schedules with such a requirement.

For some wrought alloys, the response to artificial aging is greatly enhanced if the material is strain hardened after solution heat treatment and prior to precipitation heat treatment. For 24 S (4.5% Cu, 1.5% Mg, 0.6% Mn) the increase in tensile and yield strengths is more than doubled by reductions of 6% by cold work prior to artificial aging.

Annealing. The annealing practice varies, depending on the condition or temper of the alloy. The strain hardening resulting from working wrought alloys that were originally in the soft temper, may be removed and the alloy completely softened by heating to a temperature in the range of 640 to 670 F. Heating to temperatures higher than 670 F causes partial solution heat treatment and consequently prevents complete softening; at temperatures lower than 640 F, annealing may not be complete. Casting alloys are usually annealed when in the "as-cast" condition by heating for 2 hr at 650 F.

This same practice, when applied to the wrought alloy that has been subjected to the solution heat treatment, will remove most of the effects of heat treatment as well as any subsequent strain hardening, so that the alloy is suitable for all but the more severe forming operations. However, if the heat treated alloy must be completely annealed, it must be heated for 2 hr at 750 to 800 F, then slowly cooled (not faster than 50 F per hr) until a temperature of 500 F has been reached. The rate of further cooling to room temperature is not important.

Nomenclature. The condition of heat treatment is designated by appending to the alloy number the letter T and a number that identifies the specific heat treatment. The suffix W also is a heat treatment designation, used to indicate the unstable condition immediately after solution heat treatment. For temper designations, see page 808.

Nitrate Hazard. Fused nitrate baths are commonly used in the heat treatment of steel as well as of aluminum, and it is important to guard against certain dangers in their operation. Care should be taken to prevent contact of the fused salt with carbonaceous or organic material (wood, charcoal, coke, oil or cloth) or with red hot iron or steel. Articles to be heat treated, or sludge, should not be allowed to lie on the bottom of the tank, especially if the tank is underfired, since they are likely to cause the tank to be burned through as a result of local overheating. It is important to guard against the possibility of combustible gases accumulating around the tank, and it is desirable to have at some distance from the tank a shutoff valve for the heater, which can be operated in an emergency.

Extra sacks of nitrate should be stored in a dry place and at a distance from the tank. Care should be taken not to put anything wet into the nitrate bath. If fresh salts to be added to the bath are at all wet, it is best to make the addition when the bath is frozen. In the melting of a solid bath, the salt must melt freely at the sides of the tank before melting at the bottom, to avoid generation of pressure and possible explosion. In controlling a nitrate fire, it is vitally important not to use water or any fire extinguisher containing water. Perhaps the best fire extinguisher is dry sand, a supply of which should be kept near the tank.

Joining Aluminum Alloys

By E. C. Hartmann,* G. O. Hoglund,* M. A. Miller* and P. T. Stroup*

THE METHODS described in this section for joining aluminum alloys include riveting, welding by gas, metal-arc, carbon-arc, tungsten-arc, atomic hydrogen and resistance methods, brazing by torch, furnace, or dip processes, diffusion bonding, resin bonding and soldering.

Riveting

Of the numerous wrought aluminum alloys available today, five are used commercially in the form of rivets for joining aluminum alloy structures. These various rivets are described as follows:

* Aluminum Company of America, New Kensington, Pa.

Rivets of Commercially Pure Aluminum (2 S). Rivets of commercially pure aluminum are soft and are used only for nonstructural joints in constructions involving the low-strength aluminum alloys. They are not heat treated either during manufacture or subsequently by the user, but are employed in an intermediate cold worked temper, just as when they come from the heading tools. They are readily driven cold and in the driven condition will develop an average shear strength of about 11,000 psi.

A17 S Alloy Rivets. This alloy contains nominally 2.5% Cu, 0.3% Mg, with the remainder aluminum. Rivets of A17 S are heat treated as the last step in their manufacture and are employed without subsequent heat treatment by the

user. They are driven cold and develop an average shear strength of 33,000 psi in the driven condition. In sizes ⅜ in. or less in diam, they are readily driven with ordinary equipment and can be cold driven in even larger sizes, especially if suitable squeeze riveters are available. Of all aluminum alloy rivets, those of A17 S are the most widely used in aircraft and they have been used successfully also in other types of structures where the parts to be joined are of aluminum alloy 14 S, 17 S or 24 S.

17 S Alloy Rivets. This alloy consists nominally of 4% Cu, 0.5% Mn, 0.5% Mg and the remainder aluminum. Rivets of 17 S alloy are always heat treated before use. Ordinarily they are heat treated at the plant of the manufacturer before shipment and are subsequently heat treated again by the user just before use, in order to make them soft enough to be headed easily. The treatment consists of heating the rivets to a temperature of 930 to 950 F and quenching in cold water. The rivets harden gradually at room temperature, reaching their full strength after about four days, but for a period of 1 to ▮ hr after quenching, they are soft enough to be headed without difficulty. This age hardening can be postponed and the soft condition greatly prolonged by storing the rivets at low temperature immediately after quenching. After removal from the cold storage, which is often a simple dry-ice chamber, the rivets resume their normal rate of room temperature aging. When used in the larger sizes, 17 S rivets can be successfully hot driven, if heated within the temperature range from 930 to 950 F and driven promptly after removal from the heating medium, so as to obtain a quench in contact with the material into which they are being driven. These rivets are generally stronger than A17 S rivets, but their shear strength depends somewhat on the driving condition as shown in Table I. Rivets of 17 S have been used widely in construction of aircraft and are used also in general structural applications involving parts made of 14 S, 17 S, and 24 S alloys.

Table I. Average Ultimate Shear Strengths for Driven Aluminum Alloy Rivets[a]

Rivet Alloy	Driving Procedure	Shear Strength, psi
2 S	Cold, as received	11,000
A17 S-T3	Cold, as received	33,000
17 S-T31	Cold, as received	39,000
17 S-T31	Cold, immediately after quenching	34,000[b]
24 S-T31	Cold, immediately after quenching	42,000[b]
53 S-T61	Cold, as received	23,000
17 S-T41	Hot, 930 to 950 F	33,000[b]
53 S-T41	Hot, 960 to 1050 F	18,000[b, c]

(a) These values are for rivets driven with cone-point heads. Rivets driven with heads that require more pressure, may be expected to develop slightly higher strengths.

(b) Immediately after driving, the shear strengths of these rivets are about 75% of the values shown. On standing at ordinary temperatures the rivets age harden to develop their full strength; this action is completed in about four days for rivets of 17 S and 24 S, and in about two weeks for rivets of 53 S.

(c) This shear strength is for rivets driven at temperatures from 960 to 980 F. The shear strength increases about 1000 psi for each increase of 12 F in driving temperatures. Thus, if the range of driving temperature is carefully maintained at 1030 to 1050 F, an average shear strength of 24,000 psi will be developed in the driven rivets.

24 S Alloy Rivets. These rivets have a nominal composition of 4.5% Cu, 0.6% Mn, 1.5% Mg, with the remainder aluminum. Before use they are always heated within the temperature range from 910 to 930 F, then quenched in cold water and aged at room temperature. They are supplied in the heat treated temper but should be heat treated again by the user just before driving, in order to make them soft enough to be headed satisfactorily. Rivets of 24 S alloy remain soft enough for driving for only about 90 minutes after quenching if held at room temperature; so, like rivets made of 17 S, they are usually stored at low temperature to prolong the period during which they can be headed satisfactorily. Typical driven rivets in this alloy will develop a shear strength of about 42,000 psi after about four days of aging at room temperature. These rivets are the strongest and most difficult to drive.

53 S Alloy Rivets. The nominal composition of this alloy is 0.7% Si, 1.3% Mg, 0.25% Cr, with the remainder aluminum. These rivets are heat treated by the manufacturer before shipment and are generally driven cold by the user without subsequent repetition of heat treatment. They are somewhat easier to drive than A17 S rivets and can be upset cold with ordinary driving equipment in sizes as large as ½ in. Typical cold driven rivets of this alloy develop a shear strength of about 23,000 psi. Sizes larger than ½ in. can be driven cold, especially if suitable squeeze riveting equipment is available. Where such equipment is not available, however, the rivets may be driven hot successfully by heating them to temperatures within the range from 960 to 1050 F and driving promptly after removal from the heating medium, so as to obtain a quench in contact with the material through which the rivet is being driven. The shear strength of such rivets is a function of the driving temperature and of the duration of aging after driving, as shown in Table I. Rivets may be obtained that are intended specifically for hot driving and are made of 53 S-T4 rather than 53 S-T61, because the former temper is cheaper and gives equally good results when driven hot.

Rivets of 53 S-T61 alloy and 53 S-T4 alloy have been most widely used in marine construction in conjunction with plates and shapes of 52 S, 53 S, and 61 S alloys, because in combination with these alloys the rivets exhibit excellent resistance to salt water and other types of corrosive action.

Table II. Reduction in Shear Strength of Aluminum Alloy Rivets as a Result of Use in Thin Plates and Shapes

Ratio of Rivet Diameter to Plate Thickness,[a] D/T	Percentage Loss in Shear Strength: Single Shear	Double Shear
1.5	0	0
1.6	0	1.3
1.7	0	2.6
1.8	0	3.9
1.9	0	5.2
2.0	0	6.5
2.1	0	7.8
2.2	0	9.1
2.3	0	10.4
2.4	0	11.7
2.5	0	13.0
2.6	0	14.3
2.7	0	15.6
2.8	0	16.9
2.9	0	18.2
3.0	0	19.5
3.1	0.4	20.8
3.2	0.8	22.1
3.3	1.2	23.4
3.4	1.6	24.7
3.5	2.0	26.0
3.6	2.4	27.3
3.7	2.8	28.6
3.8	3.2	29.9
3.9	3.6	31.2
4.0	4.0	32.5

(a) Thickness of thinnest plate in single shear joint. Thickness of middle plate in double shear joint.

Reduction in Shear Strength. Table II shows the reduction in shear strength of rivets which occurs with increasing ratio of rivet diameter D to plate thickness t.

Rivet Holes. Rivet holes in aluminum alloy structures may be either drilled, punched, subdrilled and reamed, or subpunched and reamed. In general, the reamed holes are much to be preferred, especially if the reaming is done in assembly, to give the holes exact coincidence. The correct clearance to use in the rivet holes depends largely on the class of work. The best clearance is the smallest one that will allow the rivet to be inserted easily without delay and is usually about 2 to 3% of the shank diameter. Hot rivets require slightly more clearance than cold ones because it is harder to handle them, and delay while inserting them into the holes must be minimized.

Flush Riveting. Countersinking of aluminum alloy plates for flush riveting should be done with a clean, sharp tool, in conjunction with a stop to prevent the plates from countersinking too deeply. The dimpling operation consists of pressing a depression into the sheet and using this recess to receive the countersunk head of the rivet.

Preparation of Faying Surfaces. For maximum resistance to corrosion, all faying surfaces in aluminum alloy riveted joints should be painted before assembly. The usual procedure is to treat the joints with one of the phosphoric acid solvent compounds and then to apply one coat of zinc chromate primer to each of the faying surfaces. The paint should be dry before the joint is assembled. The zinc chromate pigment is recommended because it imparts a corrosion-inhibiting effect to the paint in addition to the ordinary covering protection. If required, a sealing compound containing zinc chromate may be used in the joint.

Methods of Driving. Virtually all driven heads on small rivets are flat heads upset by means of pneumatic hammers or squeeze riveters. In the aircraft industry the usual procedure is to apply the pneumatic hammer to the manufactured head of the rivet and to upset the driven head against a suitable flat bucking bar or block, held firmly against the end of the shank of the rivet. An equally acceptable procedure, however, is to apply the hammer to the shank end of the rivet and to hold a suitably shaped bucking bar against the manufactured head of the rivet. In fact, this second procedure is to be preferred where the parts being riveted are quite stiff or likely to be damaged by the battering action of the pneumatic hammer.

Where flush surfaces are required, the usual practice in aircraft riveting is to insert a countersunk manufactured head into the countersunk hole and upset a small flat head on the shank end of the rivet. An equally acceptable and often preferable procedure, however, is to use some other style of manufactured head, insert the rivet from the nonflush side of the work, and upset the shank end to fill the countersunk hole. To obtain satisfactory results with this type of driving, it is necessary to leave a portion of the driven countersunk head protruding above the work and to dress this head off flush.

The intermediate sizes of rivets for purposes of this discussion range from ¼ to ½ in. in diam and are suitable for joining shapes and plates that range in thickness from ⅛ to about $\frac{7}{16}$ in. Generally, aluminum alloy rivets in this range of sizes may be driven without heating; pneumatic hammers should be used not exceeding the size corresponding approximately to a 1 to $1\frac{1}{16}$-in. bore and a 6 to 8-in. stroke. For accessible locations, squeeze riveting is preferable to riveting with a pneumatic hammer, and should be employed if the equipment is available. In riveting with a pneumatic hammer, the recommended procedure is to hold

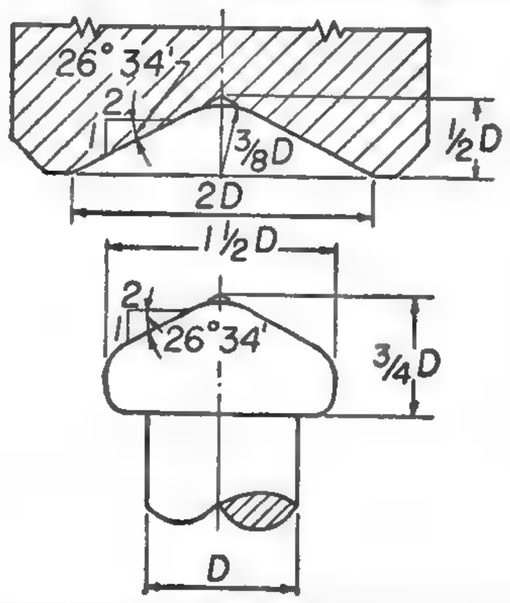

Fig. 1 Nominal dimensions of cone-point head and rivet set

the bucking bar against the manufactured head of the rivet and to upset the driven head with the pneumatic tool. If the work is not countersunk, a cone-point head of the type shown in Fig. 1 is recommended, because it requires much less pressure to drive than other types of heads, such as the round head or button head. A small flat driven head of the type used in the aircraft industry is also satisfactory if desired. Where countersunk heads are used, a 60-deg included angle of countersink is recommended, with the hole countersunk a little less than the thickness of the outside plate. In the driving of countersunk rivets, a tight rivet is usually obtained if the rivet is inserted from the side of the work that is not countersunk and is upset to fill the countersink with a slight excess of metal, which can be removed to give whatever degree of flushness is required for the particular job.

If large rivets are to be driven without heating, it is usually necessary to employ squeeze riveters, a practice that results in excellent rivets. When the cone-point and 60-deg countersunk types of driven heads are used, as described in connection with the driving of intermediate-size rivets, a squeeze riveter capacity of 30 to 40 tons is required for handling the ¾-in. rivets in the various aluminum alloys.

The use of squeeze riveters is limited by the accessibility of the part to be riveted and by the size and reach of the squeeze riveters available for a particular job. Where squeeze riveters cannot be used, it is ordinarily necessary to apply heat in driving the larger sizes of rivets, in order to make them soft enough to be upset by the pneumatic hammers. The usual procedure for hot driving aluminum alloy rivets is to heat the rivets within the normal commercial heat treating range as indicated earlier, remove them quickly from the heating medium, and insert them in the holes with a minimum loss of time so as to quench the rivets in contact with the material into which they are being driven. This procedure usually calls for an electrically heated circulating-air furnace that has good temperature control to

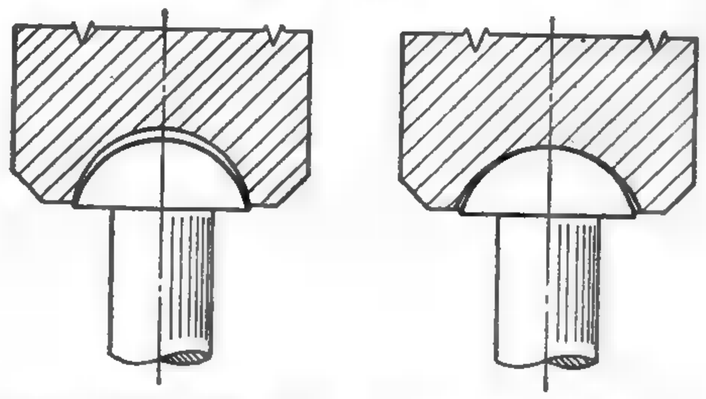

Fig. 2 (*Left*) Incorrect fit of the bucking tool on the manufactured rivet head. (*Right*) Correct fit. Clearances are exaggerated.

insure against underheating or overheating the rivets. Also this procedure requires having the furnace near the work in order to minimize the time of transfer of the rivet from the furnace to the work.

Driving Tools. The tools used for driving aluminum alloy rivets are much the same as those used for riveting other metals. Smooth polished surfaces are best for the parts in direct contact with the aluminum alloy surfaces, so that a minimum of friction is offered to the flow of metal during the upsetting operation. Pneumatic hammers should be of ample size to upset the rivet without excessive hammering. Undersized pneumatic hammers tend to peen the rivet rather than to upset it. Bucking bars should have sufficient mass, preferably distributed close to the rivet head and concentric with it. The manufactured head of the rivet should be pressed tightly against the work piece during the upsetting operation. If this is not done, or if the bucking-up set does not have sufficient mass, the manufactured head will often be separated slightly from the work piece when the driving operation is finished.

Regardless of whether a pneumatic hammer or a squeeze riveter is used, the set that is held against the manufactured head during the driving operation should be slightly wider and shallower than the manufactured head so that the initial contact will be at the end of the head directly in line with the shank, as shown in Fig. 2. This practice will prevent the shank from being driven up into the head, and thus will minimize the tendency toward the formation of a crack or fold at the junction of the shank with the manufactured head.

Welding

The common welding methods that have been adapted to the joining of aluminum and aluminum alloys, include both fusion and electric-resistance welding processes. Fusion-welded joints are made by gas, metal-arc, carbon-arc, tungsten-arc or atomic hydrogen welding. Resistance-welded joints are made by spot, seam or flash welding. In each method, the metallurgical and physical characteristics of the aluminum alloys must be considered in order to obtain

economical results and sound joints. The following sections contain a general discussion of the essential characteristics of each welding method as applied to all these alloys.

Gas Welding. The commonly used gases for welding aluminum and aluminum alloys are oxyhydrogen and oxyacetylene. With respect to soundness, strength, speed and appearance, equally good results are obtained with either gas. Standard equipment in the way of torches, hose and regulators, is suitable for welding such materials. Some welding has also been accomplished with oxypropane derivatives and with mixtures of oxygen with natural gas. Good soundness and strength have been obtained in such welds, but the use of these gases does not appear to be economical, because of the comparatively low rate of welding.

When aluminum is being fusion welded with gas, it is important that a suitable flux be used to remove the oxide coating that forms on the surface of all aluminum alloys in the atmosphere. This coating does not melt at the welding temperatures and will prevent smooth coalescence of the weld metal unless a flux is provided that will melt at a temperature somewhat lower than the welding temperatures and will break down the surface skin of oxide, permitting the liquid metal from the rod to flow into the molten parent material. A number of good fluxes are available. These are applied either dry or mixed with tap water to the consistency of ■ thick paste.

Virtually all fluxes for aluminum welding contain chlorides and fluorides, with the result that in the presence of moisture, residual deposits left on the joints after welding will attack the base metal. Thorough cleaning is especially necessary on parts that are painted, since the presence of flux will raise the paint coatings over the welds. Such action can be prevented if, immediately after welding, the parts are cleaned by scrubbing the joints in boiling water. On tanks or parts where the joints are inaccessible, the flux can be neutralized by dipping for 10 to 15 minutes in a cold solution of 10% nitric acid mixed with 0.25% hydrofluoric acid. Other acid mixtures and commercial cleaners may also be suitable for this purpose.

The proper choice of filler material for gas welding is important, particularly in the joining of alloys that have comparatively large amounts of alloying constituent. Commercially pure aluminum and metal of higher purity are generally welded with the same grade of metal as the parent material. The same practice is satisfactory for the aluminum-manganese alloy (3 S). In welding the aluminum-magnesium alloys or the aluminum-silicon-magnesium alloys, ■ filler rod containing 95% Al and 5% Si (43 S) is commonly used. This rod has a melting point substantially lower than that of pure aluminum, and permits the dissipation of some of the stress set up by solidification shrinkage and the thermal contraction that occurs in the weld zone as it cools. Cracks in the weld and the transition zone can be minimized by the use of this rod on parts that are welded in jigs to hold proper alignment.

Arc Welding in General. Aluminum and the aluminum alloys can be fusion welded with the metal arc, carbon arc, tungsten arc and with atomic hydrogen. The advantage in these processes is that the highly concentrated heated zone obtained with the arc prevents excessive expansion of the parts that are being welded, thus lessening distortion. Furthermore, the preparation of the joints for welding is simpler and the rate of welding is faster.

Metal-Arc Welding. Because of the relative difficulty of controlling the arc, it is not practical to butt weld material that is less than 0.081 in. thick, or to fillet weld joints on plate that is less than ⅛ in. thick. The soundness of the welds, particularly in thin material, is not equal to that of torch welds. Arc-welded joints are equal in strength to torch-welded joints; however it is difficult to obtain liquid-tight or gastight joints in material less than ¼ in. thick.

The standard electrodes for welding aluminum are designed to be used for direct current. Ordinarily this current is obtained from a d-c motor-generator set used for welding steel. Current obtained by rectifying alternating current is also satisfactory for this purpose, but the standard 60-cycle alternating current is not suitable for use with the present electrodes. However, if high-frequency current is superimposed on standard 60-cycle alternating current, the standard electrodes will function satisfactorily.

The proper polarity should be determined by trial on the joints to be made. The capacity of the equipment and the size of electrode are determined by the thickness of the material to be welded. Table III provides approximate machine settings and electrode sizes for welding the various thicknesses of aluminum.

Table III. Electrode Size and Machine Settings for the Metal-Arc Welding of Aluminum

Thickness, inch	Electrode Diameter, inch	Current, amperes
0.081	⅛	55 to 65
0.102	⅛	65 to 75
0.125	⅛	75 to 85
3/32	⅛ or 5/32	85 to 100
1/16	5/32	100 to 125
¼	5/32 or 3/16	125 to 150
5/16	3/16	150 to 175
⅜	¼	175 to 200

Unless a suitable flux is provided, the oxide coating present on the electrode and the parent material will prevent coalescence of the weld metal. Consequently, successful results are most easily obtained by using a coated electrode on which a heavy coating is provided that functions both to remove the coating on the metal and to stabilize the arc. Since the 43 S alloy provides superior fluidity at the welding temperatures, this alloy is used for the filler material in all the electrodes that are commercially available.

Carbon-Arc Welding. Carbon-arc welding is an alternative arc-welding method suitable for all the weldable aluminum alloys in any thickness not exceeding approximately ½ in.

Equipment for making carbon-arc welds is the same as that used for metal-arc welds except that a-c as well as d-c power is suitable as a source of welding current. In manual welding, more training and experience are needed before an individual becomes adept at making fillet and butt welds. Welding is almost always done in the downhand position.

A filler rod coated with flux is necessary in carbon-arc welding and electrodes for metal-arc welding are frequently used. This is satisfactory with respect to strength and soundness, but it is more economical to use a rod specially prepared for carbon-arc welding with a thinner coating of flux. Such a filler rod will make 20 to 30% more footage of weld.

The carbon arc has also been adapted for automatic welding. The most suitable type of equipment is that in which the arc length is adjusted automatically and an a-c field is superimposed around the carbon.

The method has been used for seams and head welds in vessels such as chemical tanks and tank cars. No preparation of edges is required for butt joints ½ in. thick or less. Back-up below the joint and a clamping device are necessary to maintain alignment of the edges. Filler wire and powdered flux are fed to the weld automatically. The alloy of the wire should be the same as that used for other welding methods. It is ordinarily desirable to employ hard drawn wire instead of annealed wire in order to get a uniform feed in the wire-feed mechanism.

Tungsten-Arc Welding. The only fusion welding process found suitable for welding aluminum alloys without the use of a welding flux is tungsten-arc welding in an argon atmosphere. This process, introduced during World War II, widens the field for application of welding. Welds made properly by this method are relatively free from discontinuities such as oxide film, porosity, or lack of fusion. The characteristics of welds made by this method are a sound weld structure, uniformity in strength of the joints, improved ductility across welds in the heat treatable alloys, and smooth appearance.

The procedure is carried out with standard a-c welding equipment supplied with superimposed high-frequency current on the welding circuit to establish and hold a steady arc. Filler wire of the standard compositions is fed into the joint. The smooth coalescence and viscosity of the weld metal make it feasible to weld in the overhead and vertical position as well as downhand. High-purity argon is fed

through a cup surrounding the tungsten electrode, so that it blankets the arc and the molten metal.

Preparation of the surface for welding requires thorough cleaning and removal of the oxide coating. Dirt and grease are usually removed by solvent methods; then the edges and the surface near the weld are cleaned further with a wire brush. No cleaning is required after the weld has been made.

Atomic Hydrogen Welding. The atomic hydrogen process involves drawing an arc between two tungsten electrodes in a hydrogen atmosphere. The arc, independent of the work material, can be handled in much the same manner as a welding torch and may be moved away from or toward the joint, according to the need. This flexibility is valuable in making many types of joints.

In the atomic hydrogen process a good grade of aluminum flux should be used; a number of such fluxes are available. When mixed with water to the consistency of a thin paste, the flux should be applied to both the filler rod and the seam.

As in gas welding, the choice of filler material is important in this process and follows the same rules. Where the thickness of the metal being welded is sufficient to allow the manipulation, the filler rod may be inserted into the molten pool and moved back and forth to assist in breaking up the oxide film that is present. Aluminum flows readily after reaching the molten state, so care must be used to keep the molten metal from falling through. To prevent this, particularly with plates thicker than $\frac{3}{16}$ in., it is desirable to back up the weld.

In atomic hydrogen welding, cracking may be avoided usually if a short weld, about an inch long at the beginning of a seam, is made and allowed to cool before proceeding with the remainder of the seam. Parts should be preheated to approximately 425 F before welding, and should be allowed to cool slowly after the weld is completed. Sawdust sprinkled near the seam will char at about the correct preheating temperature. A powdery layer of oxide and flux gradually accumulates on the electrode clamps and may cause the arc to flow between the tips of the electrode holder instead of between electrodes, with resulting damage to the tips. If the ends of the electrode clamps are dipped into water occasionally, this accumulation will be dissolved.

Welding of Castings. The welding of aluminum alloy castings is a useful and economical procedure for the foundryman and fabricator. One of the chief applications is in salvaging castings that have foundry defects. Another important use is in repairing castings that have been cracked or broken. The welding of castings is of interest to the fabricator also because aluminum alloy castings can be welded satisfactorily to wrought alloy sections, thus forming combinations of thick and thin metal.

In general, the welding of aluminum alloy castings requires a technique similar to that used for aluminum sheet and other wrought products. However, it is necessary to consider carefully the susceptibility of many castings to thermal strains and cracks, because of intricate design and varying thickness of section. In addition, many castings in highly stressed structures depend on heat treatment for strength, and welding, as previously indicated, tends to destroy the effect of the initial heat treatment. In these instances, unless the casting or assembly can be heat treated again, welding is not recommended. When it is possible to heat treat the casting or assembly after welding, the strength can be restored substantially.

The data for preparation of edges, machine settings, and general recommendations for gas welding, arc welding, and resistance welding apply to the welding of castings. Some additional precautions are sometimes required, in regard to chipping or removing defects. Since many castings have intricate shapes, preheating is frequently desirable to reduce differentials in temperature. In this connection, slow and uniform cooling to room temperature is as important as preheating for the elimination of thermal strains that occur because of changes in shape or section.

Castings should be designed so that the parts to be joined by welding have as nearly the same thickness as is practicable. Rather than to attempt the welding of a thick section directly to a wrought or cast part that has a relatively thin section, it is better to provide a gradual taper on the thick section and to weld at a point where the thickness approximates that of the lighter piece. Cast fittings to be welded to light-gage wrought parts, should be provided with flanges tapering to the thickness of the wrought section. Consideration of these factors in the design of castings will greatly facilitate the welding of assemblies involving light and heavy sections.

Resistance Welding. The aluminum alloys are joined in production by spot, seam and push or flash welding methods. Sound joints can be made by resistance welding if proper equipment is used; if the surface of the metal is prepared correctly; and if the proper machine settings are used in operating the equipment.

Equipment for spot welding aluminum is not basically different from that used for welding other metals, except that more rigid control of time and pressure is desirable and the current should be integrated in smaller steps. When timing is considered, best results are produced—particularly on light-gage material—with electronic equipment that ensures delivery of a definite number of cycles, and eliminates undesirable transients in the secondary circuit by making and breaking the current at the zero point on the a-c wave. Good results can also be obtained with timers of the contactor type, controlled either mechanically or electronically. Experience has shown also that mechanisms utilizing hydraulic or pneumatic pressure are superior for spot welding the aluminum alloys, because duplication of pressure at the tips can be obtained most accurately. Current in the secondary circuit must be relatively high in equipment for spot welding the aluminum alloys, because of the high thermal and electrical conductivity of these materials. This factor of machine design should be considered in the preparation of machine specifications, in order to ensure that sufficient current is available.

The electrical demand in the spot welding of aluminum may be reduced by the use of a magnetic-energy-storage type of equipment that stores the welding energy in an inductor transformer by establishing a direct current between 100 and 400 amp in the primary winding of this transformer. When the current is interrupted by a magnetic contactor, a high value of current is established in the secondary circuit, and through the work that is being welded. This current decays to a low value in from 0.01 to 0.05 sec. Equipment incorporating this process is also provided with an electrode force system that permits the welding force to be varied during the welding operation. The combination of a short-time welding-current impulse and a varying force results in welds of excellent appearance and of sound structure.

The direct current used in the primary of the inductor transformer is ordinarily obtained by rectifying a three-phase 440 or 220-v shop supply. The maximum demand for power with this type of equipment is about one-tenth that of a-c equipment, welding the same thickness of material, because the energy is obtained by drawing a lower power for a much longer time.

The condenser-energy-storage equipment utilizes static condensers to store the energy used for welding. The three-phase shop power is stepped up in voltage and rectified so as to charge the condensers to a voltage from 1000 to 3000 v. When this bank of charged condensers is connected to the primary of the special welding transformer, an impulse of welding current rises rapidly to its maximum value and decays to zero at a somewhat slower rate. For welding with this equipment, a constant high value of welding force is generally used. Occasionally a higher force is used at the end of the welding procedure, to provide a forging action on the solidified weld metal. Welds produced with this type of equipment are excellent in appearance and very sound in structure. Also, the maximum demand on the power system is about one-tenth of that required when a-c welding equipment is used for joining the same thickness.

For all these forms of welding equipment, the power required depends on both the material to be welded and the throat area of the welding machine. To obtain adequate power and reduce the cost of the welding equipment, it is advisable to use a machine with the shortest length of arms and the minimum arm spacing compatible with the shape of the work pieces to be welded.

Preparation of the surface of the material is significant,

particularly with respect to welding cost. The oxide coating of some alloys is sufficiently resistant to passage of the welding current to cause surface heating that will alloy the welding tip materials with the parts. This is particularly true of the heat treated alloys, in which the thermal operations required during heat treating increase the thickness, and consequently the resistance, of the surface oxide coatings. From any alloy that wears away the tip excessively, the oxide coating should be removed with steel wool, emery cloth, or a chemical etch before welding.

In setting up a welding operation it is essential to use welding tips that will maintain consistent distribution of current and pressure during successive welds. The common method of dressing tips with a file is not suitable for spot welding the aluminum alloys. Good results in practice have been obtained by machining the tip to a contour that can be restored periodically with a fine grade of emery held in the fingers. A tip with a hemispherical end is ordinarily employed. Materials for tips to be used in spot welding should have a conductivity greater than 75%, and a hardness exceeding Rockwell B 60. To make proper machine settings it is essential to calibrate the current and pressure delivered by a machine.

Table IV

Machine Settings for Spot Welding Aluminum Alloys

Gage B & S No.	Gage Inch	Time, cycles	Current, amperes	Electrode Pressure Min, lb	Electrode Pressure Max, lb
26	0.016	4	14,000	200	400
24	0.020	6	16,000	300	500
22	0.025	6	17,000	300	500
20	0.032	8	18,000	400	600
18	0.040	8	20,000	400	600
16	0.051	10	22,000	500	700
14	0.064	10	24,000	500	700
12	0.081	12	28,000	600	800
10	0.102	12	32,000	800	1000
8	0.128	15	35,000	800	1200

In seam welding, a special application of spot welding, rolls are used for electrodes and the current is applied intermittently. Machine characteristics, as outlined above, apply as well to seam-welding equipment, except that successful results have been obtained only with electronic timing devices. In the making of liquid-tight or gastight joints, the timing cycle is adjusted so that the current is on not more than 30% of the time. By adjustment of the timing cycle and the speed of the rolls, overlapping or intermittent welds can be made. Machine settings for seam welding depend on the gage, temper and alloy to be welded.

Electric Butt Welding. The common alloys, 2 S and 3 S, and high-purity aluminum are more readily electric butt welded, but all the wrought alloys can be welded by this method if a welding machine of proper design is available.

Simple cylindrical and rectangular sections of aluminum can be push welded. The parts to be welded are clamped in dies and pressure is applied before the application of power causes melting at the surface of the aluminum and softening of the metal near the plane of contact. The joint is held under pressure by the dies so that the molten and soft metal are squeezed out of the joint. Power is cut off after a predetermined die travel or application of a definite number of cycles of current. The weld freezes rapidly because of conduction of heat away from the joint.

Push welds require excellent fit between the pieces being welded and between the pieces and the clamping dies. Equipment for such welding is characterized by high current capacity and rapid free movement of the movable die.

The flash butt-weld process is adaptable to welding complicated extruded shapes of aluminum as well as the simpler cylindrical and rectangular shapes. Parts to be welded are clamped in dies and power is applied before the parts are allowed to come in contact. A motor-driven cam imparts an accelerated motion to the movable die, and thus brings the dies together. Flashing is continued from ½ to 1½ sec, during which time from ¼ to ¾ in. of aluminum is flashed from the parts being welded. The flashing period is terminated when the power is cut off almost simultaneously with a sudden increase in velocity of the moving die. The ends of the parts being welded are forced together and the weld freezes rapidly bcause of conduction of heat to the dies.

Good fit between the parts being welded is not necessary. Dies should fit the aluminum sections well enough to provide mechanical support for projections or thin sections, and clamping pressure must be high enough to prevent slippage during the final push-up period.

The relations among welding time, die motion, die spacing and welding current are varied for each section and each alloy of aluminum that is welded.

The weldable aluminum alloys are grouped as shown in Table V, and special characteristics of welding as applied to these groups are described in the following.

High-Purity Aluminum. Occasionally it is necessary to use material of purity higher than that of commercially pure aluminum, in order to obtain greater resistance to certain types of chemical attack. As a typical example, many

Table V. Process Chart for Welding Aluminum Alloys

Metal or Alloy	Gas	Arc	Spot	Seam	Butt or Flash
High-purity aluminum	A	A	A	A	A
Commercially pure aluminum (2 S)	A	A	A	A	A
Al-Mn alloy (3 S)	A	A	A	A	A
Al-Mg-Cr alloy (52 S)	B	A	A	A	A
Al-Si-Mg alloys (53 S, 61 S, 63 S)	B	A	A	A	A
Al-Cu-Mg-Mn alloys (14 S, 17 S, 24 S, A17 S)	No	B	B	B	A
(Alclad 17 S, Alclad 24 S)	No	B	A	A	A

A, welds can be applied generally on a commercial basis.
B, commercial welding depends on design or special technique.
No, commercial welding is not feasible.

of the storage or fermenting tanks employed in the brewery industry are made of aluminum having a purity of 99.5%.

Fusion welding of high-purity aluminum requires no special treatment with regard to welding technique as far as equipment, preparation of joints, or machine settings are concerned. In order to produce welds that have resistance to corrosion comparable with that in the parent material, a filler wire of the same composition as the parent material should be used. This requirement is frequently fulfilled by shearing strips from the parent material. If joints in these materials are to be made by metal-arc or carbon-arc welding, special flux-coated electrodes with a filler material of high-purity wire should be obtained.

Welds in these materials are characterized by comparatively high ductility and dressing operations are usually carried out by hammering. A tensile strength across the welds equal to the strength of the annealed temper of the parent material is obtained in fusion welded joints, regardless of the temper of the material prior to welding. Sound welded joints can be made in any of the commercial forms of these materials.

Resistance welding of these materials is easily accomplished by spot, seam or butt welding and no special practices are required. The ability of these welds to withstand corrosion is not inferior to that of the parent metal.

Some difficulty may be experienced if spot or seam welding is attempted as a method of joining high-purity aluminum in the soft temper to material that is heavier than 0.100 in. thick. The cause of the trouble is that the hardness of these materials in the soft temper is not sufficient to prevent the welding electrodes from deforming the surface, with consequent spreading of the current and pressure distribution during the welding cycle. This results in weak and inconsistent welds—but not in the intermediate or hard tempers of these materials.

Commercially Pure Aluminum (2 S). Commercially pure aluminum, readily weldable by all methods, is widely used for making dairy and chemical tanks wherever the mechanical properties are adequate.

This material can be both gas welded and arc welded, and commercially parts have been welded that range in thickness from 0.020 to 1 in. Butt welds are characterized by high ductility in the welds and excellent resistance to impact or shock loading. A strength equal to the tensile strength of the annealed material is obtained in the welds.

Commercially pure aluminum is generally employed as a

filler material when making welds, and considerable testing and practical use have indicated that resistance to corrosion of such welds is substantially equal to that of the parent material. Metal-arc welding is usually done with standard flux-coated electrodes containing 43 S filler rod. However, where maximum resistance to chemical attack is important, a special coated electrode should be used, containing commercially pure aluminum filler material.

All the commercial forms of commercially pure aluminum are spot, seam, or butt welded in production. No special technique is required for welding these materials, and because of the excellent surface present on commercially pure aluminum, this is probably the most economical alloy to use with regard to cost of resistance welding. It is also common practice to use resistance welding for joining together articles made of commercially pure aluminum and for cast parts in which the composition has been varied to improve mechanical properties or casting qualities.

The remarks concerning the welding characteristics of the annealed temper, above, apply also to commercially pure aluminum.

Al-Mn Alloy (3 S). This alloy is substantially the same as commercially pure aluminum from the standpoint of welding, except that the mechanical properties of both the parent material and the welded joints are higher.

Fusion welding of this alloy is widely practiced where a higher strength is required than can be obtained in welded parts made from commercially pure aluminum. The previous remarks about filler wire and resistance to corrosion apply as well to this material.

Resistance welding of this alloy is similar to that of commercially pure aluminum. The strength of the welds, however, is higher.

Al-Mg-Cr Alloy (52 S). By the alloying of aluminum with magnesium and chromium, a material is available that has considerably higher mechanical properties than can be obtained in the materials mentioned in preceding paragraphs. This introduces problems that are discussed below, particularly from the standpoint of fusion welding.

In fusion welding, this material is more sensitive to the application of the welding heat, and as a result of thermal contraction and solidification shrinkage, cracks may occur when the weld cools. This condition is minimized if the filler material that is used has a lower melting point than the parent material, and virtually all gas welding is done with a 43 S filler rod. Cooling cracks are less likely when the parts are thin enough for welds to be made in one pass. Consequently, most commercial applications have been made on material less than ¼ in. thick. Welded joints in thicker parts usually require preliminary trial to determine a method that will cause the least stress in the welds during the cooling period.

The strength of welds in this alloy is generally equal to the strength of the annealed material, but the elongation in the welds is less than that obtained in commercially pure aluminum or the aluminum-manganese alloy.

The above remarks do not apply to joints made by the metal-arc or carbon-arc welding processes, in which the welding heat can be concentrated within a narrow zone and difficulties from cracking as the weld cools are virtually eliminated. The standard arc-welding technique using a 43 S filler wire in the electrodes is commonly employed for arc welding alloy 52 S.

This alloy can be spot, seam, or butt welded readily, and because of the high strength and hardness, no difficulty is experienced with any temper. Some of the commercial forms, particularly the annealed sheet, are covered with an oxide coating that will cause wear of the welding electrodes unless it is removed by mechanical or chemical means before welding. The strength of spot and seam welds in this alloy is higher than that obtained with the materials previously mentioned. The spot welding of this alloy has been practiced widely for assembling airplane gasoline tanks.

Al-Si-Mg Alloys (53 S, 61 S, 63 S). For strength, these alloys rely on operations in which the material is treated thermally so that the metallurgical structure is arranged to obtain comparatively high mechanical properties. The application of welding heat may partially obliterate the heat treated structure and lower the properties.

All these alloys can be joined with the welding torch so that sound welds with consistent strength are obtained. However, in this method of welding, the heat affects a width in the parent material from two to five times the thickness of the material. After welding, a repetition of the heat treatment will increase the strength of the joint, but because of the cast structure in the weld, a strength equal to that of the parent material is not obtained. The strength of a gas-welded object made of these alloys is usually not predictable, since the annealing effect of the welding heat depends on the amount and location of the welds in the parts. Mechanical tests are usually performed on the welded parts to determine the suitability of the welded assembly for the service intended.

The welding technique is substantially the same as for other materials and the resistance to corrosion of welded joints is good. Filler wire of 43 S is ordinarily used.

In arc welding, less difficulty is experienced from cooling cracks when these alloys are assembled with the metal arc or carbon arc, because of the comparatively narrow zone affected by the welding heat. However, the strength of the welds is approximately the same as that obtained with the gas torch, and the previous remarks made in connection with gas welding apply as well to arc-welded joints. Flux-coated electrodes containing 43 S filler wire are used for arc welding these Al-Si-Mg alloys.

For these alloys resistance welding is widely used, particularly where structural sections are spot welded to sheet panels to stiffen the panels. Sheet of 52 S alloy is commonly spot welded or seam welded to extruded shapes made of one of the Al-Si-Mg alloys. High mechanical strength is obtained with this combination and the resistance of the welds to corrosion is as good as that of the parent material.

Because of the heat treatment of these alloys, an oxide coating is usually present on the surface, which interferes with the passage of the welding current. Before welding, in order to prevent surface heating between the parts and the welding tips, mechanical or chemical cleaning operations are performed on the surface that contacts the welding tips. Occasionally, it is desirable also to remove the coating from one or both of the faying surfaces.

Al-Cu-Mg-Mn Alloys (14 S, 17 S, 24 S, A17 S, Alclad 17 S, Alclad 24 S). This group of materials includes the aluminum alloys in which the strength is increased to a maximum by heat treatment. With two exceptions, the effect of welding is to reduce the resistance to corrosion and the mechanical strength. Consequently, these materials are not used extensively in welded parts.

In view of the fact that no greater strength can be obtained when welding these alloys than can be obtained with 61 S and 53 S, and that the resistance to corrosion is substantially lowered by gas welding, these alloys cannot be recommended for joining by gas welding.

The previous remarks about gas welding apply as well to metal-arc and carbon-arc welds made in these alloys. However, these alloys can be arc welded in a limited number of instances when the welds can be placed at locations in the structure where the stresses are low. Because of the effect of the welding heat on the structure of the alloy, it is suggested that welded parts be tested before use or that the problem be submitted to an organization familiar with handling these alloys.

Spot, seam or butt welding can be used for assembling these alloys with good results in regard to static mechanical strength. Insufficient information is available to permit making general conclusions concerning the qualities of resistance welds under shock or vibrational loading.

Exposure tests of resistance welds made in these alloys have indicated, with the exceptions mentioned below, that the resistance to corrosion of the welds is not equal to that of the parent material. It follows that, under corrosive conditions, protective paint is essential to prevent deterioration in the joints.

In some applications, particularly aircraft structures, it is important that the resistance to corrosion of spot welds should be as good as that of the parent material in the high-strength alloys. Such resistance is obtained by providing a surface of high-purity aluminum on the alloys, thus protecting the material from corrosive influences. For this purpose, Alclad 17 S and Alclad 24 S

have been produced, and considerable testing of spot welds exposed to corrosive conditions has indicated that welds having corrosion resistance equal to that of the parent material can be produced in these alloys.

Brazing

Methods of Brazing. Aluminum brazing differs from welding, in that special fluxes and filler materials, having a melting point lower than that of the alloys being joined, are used for making the joints without melting the parent parts. The parts produced are similar to welded parts in the sense that the product is 100% aluminum alloy, a circumstance beneficially reflected in the matching of color and also in strength, resistance to corrosion, and ability to be anodically coated and electroplated.

The three procedures most widely applied in brazing aluminum are torch brazing, furnace brazing, and flux-bath or dip brazing. Torch brazing is similar to gas welding in that the heat required for melting the filler material is applied to the joint locally with a welding torch, using either oxyhydrogen, oxyacetylene or oxy-natural gas flames. Furnace brazing is done by applying a flux to the work pieces, assembling the parts and raising the temperature of the entire assembly or batch of assemblies in a furnace to a point that will cause the filler material to melt and flow into the joint without melting the parent parts. Dip brazing is accomplished by assembling the parts and dipping a particular area or the complete unit into a bath of molten flux held at a temperature higher than the melting point of the filler material but lower than the melting point of the parent alloys.

Materials Available. A number of fluxes are available for the brazing processes. Alcoa No. 33 flux is used for torch brazing all alloys and furnace brazing the alloys that can be brazed and heat treated. Alcoa No. 30 flux is used for furnace brazing where maximum flow of metal is required, particularly on heavy sections, at temperatures higher than 1100 F.

Several types of aluminum brazing sheet are available. This brazing sheet is a duplex product consisting of an aluminum alloy core with a thin layer of aluminum brazing alloy on one or both surfaces. When the sheet is properly heated to a temperature higher than the melting point of the coating alloy and lower than the melting point of the core, in the presence of an appropriate flux, a portion of the coating melts and flows into the nearest capillary spaces. Where aluminum brazing sheet can be used, the advantage is that no preplacement of brazing alloy is necessary, in the form of wire rings, washers or such. The proper fluxes, filler alloys and brazing temperatures are shown in Table VI for various materials to be brazed.

Design of Joints. Lock-seam, tee, line-contact, or lap joints, rather than butt or scarf joints, are ordinarily used with brazing. When added filler metal is used, clearance between the parts is necessary for the flow of the filler material. Clearances are of the order of 0.006 to 0.010 in. for laps smaller than 0.25 in. and as great as 0.025 in. for longer laps. For brazing sheet, the principle of line contact should be employed; that is, the sheet should touch the part to which it will be brazed along a line.

Alloys 2 S, 3 S and metal of higher purity are the only ones of the wrought alloys not adapted to heat treatment, for which commercial brazing processes have been developed. Since brazing temperatures are higher than annealing temperatures, designs involving the use of alloys that cannot be heat treated must be based on the annealed temper of the material. Alcoa 53 S, 61 S and No. 21 and 22 brazing sheet are the alloy products that can be heat treated, for which satisfactory brazing techniques have been developed. The temperature of brazing can also effect the heat treatment so that quenching after brazing, followed by artificial aging, will produce the maximum properties.

Brazing Technique. The parts to be brazed, as well as the filler material, must be thoroughly cleaned and freed from dirt and oil in order to obtain satisfactory results. The removal of foreign material is usually sufficient cleaning for torch-brazed joints. However, before furnace brazing or dip brazing, it is best to use a chemical cleaning method. A satisfactory procedure is to immerse the parts for about 30 sec in a 5% solution of sodium hydroxide at 150 F, then to rinse in water, to dip in a solution of 10% or more nitric acid, and finally to rinse thoroughly in water again.

Furnace brazing consists in assembling the parts with filler material in place, applying flux, and putting the assembly in a furnace operating at the required temperature, for a period sufficient to cause the flux and filler material to melt and flow into the joints. The brazing flux is usually applied by dipping the parts into a suspension of three parts of flux in one or more parts of distilled water, or by brushing or spraying this material onto the parts.

Dip brazing differs from furnace brazing in that it is not necessary to apply the brazing flux in a separate operation. Held in a suitable rack, the assembly, with brazing alloy in place, is dipped into molten flux. As in furnace brazing, the temperature is such that the brazing alloy melts and flows into the joints without melting the parent parts. A nickel pot that is heated externally or a ceramic pot that is heated internally may be used to hold the flux.

It is always necessary to remove the flux from the parts after brazing. Immersion in boiling water immediately after the brazing operation, generally removes most of the flux. If such a treatment is likely to distort the parts, they should be cooled first to room temperature and then immersed in boiling water. After most of the flux has been removed in boiling water, the parts are immersed in an acid solution and are then rinsed thoroughly. Suitable acid solutions are concentrated nitric acid, 10% nitric acid plus 0.25% hydrofluoric acid, or 10% nitric acid plus 10% sodium dichromate.

Mechanical Properties and Resistance to Corrosion. The wrought alloys that cannot be heat treated will be in the annealed temper after furnace or dip brazing. The wrought alloys suited to heat treatment may be quenched from the brazing operation and artificially aged or may be cooled in air, then heat treated again and allowed to age. Alloy 61 S, for example, when quenched from the brazing operation and afterward artificially aged, will exhibit a tensile strength of 45,000 psi, a yield strength of 40,000 psi and an elongation of 9% in 2 in. Under the same conditions, Alcoa No. 21 and 22 brazing sheet will develop a tensile strength of 35,000 psi, a yield strength of 29,000 psi and an elongation of 9% in 2 in.

Torch-brazed aluminum alloy joints have essentially

Table VI. Filler Alloys, Temperatures and Fluxes for Brazing Various Aluminum Alloy Products

Material Being Brazed	Filler Alloy	Brazing Temperature, deg Fahr	Brazing Flux	Type of Brazing
2 S, 3 S, 406	43 S wire	1160 to 1185	No. 33	Torch
	No. 711 brazing sheet	1160 to 1185	No. 30, 34, 53	Furnace
	No. 713 brazing sheet	1160 to 1185	No. 34, 53	Dip
53 S	No. 717 brazing wire	1060 to 1090	No. 33	Torch
61 S	No. 717 brazing wire	1060 to 1090	No. 33	Furnace
			No. 34, ■	Dip
No. 1, 2 brazing sheet	Present as coating	1160 to 1185	No. 34, 53	Furnace
			No. 34, 53	Dip

			No. 34, 53	Dip

the same tensile and flexural fatigue properties as torch-welded aluminum joints in the same alloys.

In general, the resistance of brazed joints to corrosion is comparable to that of welded joints in the same alloys.

Diffusion Bonding

The methods of affecting a bond between two similar or dissimilar metallic surfaces, without the presence of a liquid phase, is termed "diffusion bonding".

For the diffusion bonding of aluminum parts, the first requisite is to have a minimum of oxide film on the surface. The parts are then brought into intimate contact by the suitable application of high pressures, and are heated to an elevated temperature in order to permit some deformation at the joint. The period of time required for permitting this deformation to take place, decreases with increasing temperature and pressure. The exact conditions of time, temperature and pressure depend on the surface preparation and the alloy used. Suitable pressures are of the order of 5,000 to 10,000 psi, with temperature in the range from 800 to 900 F and deformation from 25 to 50%. One production unit has operated under these conditions with a time cycle of 30 sec per assembly.

It is necessary to remove as much of the oxide film as possible and to permit deformation during bonding, so that the remaining oxide is broken up and extended, thus permitting intimate contact of metal against metal. Experience indicates that a chemical treatment of aluminum surfaces, with or without subsequent scratch-brushing, greatly reduces surface oxide film. When the surfaces are relatively free from oxide film they should be brought together as soon as possible, under conditions that will not cause reoxidation.

Resin Bonding

Resin bonding may be broadly defined as a process of making joints between metal and metal, or metal and nonmetal, by means of organic adhesives or resin cements, usually with the application of heat and pressure. The bonding may be carried out in the range from room temperature to about 500 F, depending on the adhesive used and the character of the surfaces to be bonded. The process can therefore be classified with low-temperature joining methods. Because the adhesives are organic in nature, the strength of resin-bonded joints decreases with any increase in temperature above room temperature.

Three basic types of cements are used for the resin bonding of aluminum alloys. Vulcanizable cements contain natural or synthetic rubber, alone or in combination with synthetic resin materials. Thermosetting cements are based on types of plastics that will not resoften, with or without additions of synthetic rubbers. The thermoplastic cements are generally solutions of plastic materials that will soften reversibly.

The surfaces to be bonded must be free from foreign matter, grease and such, but not necessarily free from uniform and stable oxide films. Solvent or vapor degreasing is sufficient in some instances; in others, particularly with the heat treatable aluminum alloys, it is desirable to use a chemical treatment—for example, a cleaner of the phosphoric acid type. Thermoplastic cements may be applied to the clean dry surfaces in the form of a solid, a hot melt or from solution; thermosetting and vulcanizable cements are almost always applied from solution, although films or tapes can sometimes be used. Solutions are applied by brushing, dipping, spraying, roller coating or like operations. The solvent is permitted to evaporate at room temperature or higher. The faying surfaces are then brought together, while subjected to the recommended temperature for the particular adhesive being used, under sufficient pressure to permit the cement-coated surfaces to come into contact and fuse or bond together. For thermoplastic cements, the characteristics of flow are such that with relatively thick films, the pressure may be quite low and the period of time only that required to bring the bond to the joining temperature. The heat-setting cements generally require pressures between 25 and 500 psi, temperatures from 200 to 400 F and time periods of 10 to 30 min. A common method for obtaining such conditions is to place the parts together between electrically heated platens in a hydraulic press.

It is always advisable to design resin-bonded joints so that the principal stresses are in shear. Furthermore, it must be borne in mind that although the failing load of an assembly will be proportional to its width parallel to a simple lap joint, the failing load will not be proportional to the amount of overlap at the joint, because of unbalanced strains. Such unbalanced strains may be minimized by using scarf, strapped or double lap joints. The failing stress of resin-bonded assemblies that contain simple lap joints, will increase with increasing thickness of the component sheets; for example, from 2500 psi for sheet 0.028 in. thick to 5300 psi for sheet 0.192 in. thick. In resin-bonded joints in work pieces made of Alclad 24S-T4, 0.064 in. thick, the tensile shear strength decreases from about 5000 psi for a 0.25-in. overlap to about 3800 psi for a 1.0-in. overlap. Scarf joints in 0.064-in. Alclad 24S-T4 have given shear strengths of 6400 to 6700 psi.

Some adhesives are associated with rather severe corrosion at faying surfaces, when lap joints are immersed in sea water for several months; other adhesives fail without visible corrosion. A few adhesives resist an exposure to sea water quite satisfactorily for at least a year. In applications where high resistance to corrosion is needed, it is advisable to paint the resin-bonded joint.

Soldering

Any ordinary soldering iron (soldering copper), heated by gas or electricity, may be used on aluminum in the same manner as on the other materials, such as copper, brass and iron, except that before the copper tip is used, it should be tinned with ordinary lead-tin solder, and that an aluminum solder must be used for the joining. As for other metals, flame or torch methods may be used for soldering aluminum, with the added precaution that the flame should be directed on the side of the part opposite the joint or near the joint, so that the heat to melt the solder is supplied by conduction, and so that the flame does not come in direct contact with the flux and solder; a hot plate is particularly useful in this connection. A small quantity of the flux is applied to the joint or to the solder wire and the joint is made by means of a soldering iron, flame or hot plate. No rubbing is needed; the technique resembles that for other metals.

For accessible surfaces, it is common practice to cause the molten solder to wet or to alloy with the aluminum by a method involving mechanical abrasion or friction. In general, the solder is melted on the aluminum surface and the surface is rubbed or otherwise abraded beneath the molten solder in order to remove the oxide film and to allow the solder to adhere to the surface. Mechanical friction can be produced by a soldering iron, scraper, steel wool, wire brush, or sometimes by the solder stick itself. After the surfaces are alloyed to the solder, they may be joined together by placing them in contact and subjecting them to heat; additional solder may be added if required. Aluminum surfaces that have been properly alloyed to an aluminum solder by any of the common methods may then be joined by ordinary soft solders and fluxes.

Soldered joints can be used for joining tubing, sheet, extruded shapes or any of the commercial forms of 2S or aluminum of higher purity—3S, 53S and 61S. Alloy 52S has rather poor soldering characteristics unless the parts are cleaned before applying the solder; a brief dip in 5% hydrofluoric acid has been found suitable for such cleaning. Alloys such as 56S, which contain substantial amounts of magnesium as an alloy constituent, have poor soldering characteristics.

Soldering can also be used for joining other metals to aluminum, either directly or by plating the aluminum first with copper. For example, joints can be made to copper, brass, iron, steel, nickel and other metals. Applications such as the joining of copper sleeves to transmission line fittings have been successful for many years.

The resistance to corrosion of soldered joints is the most important single factor to be considered before the

use of soldering is attempted for purposes of production. Since all solders are composed of metals possessing solution potentials different from that of aluminum, corrosion failure of the joint may occur in the presence of an electrolyte. Many salt-type fluxes leave a residue that accelerates corrosion, and for this reason such fluxes should not be used. The life of the joint will depend almost entirely on the conditions to which it is exposed. Experience indicates that if a joint can be kept dry, it will last indefinitely. When resistance to corrosion is important, brazed, welded or riveted joints should be considered, or a paint coating should be applied to the soldered joint.

Machining Aluminum Alloys

By R. L. Templin*

ALUMINUM and most of its commercial alloys have good machining characteristics, but these characteristics differ somewhat from those of the other commonly used metals. Although the tools ordinarily used for cutting steel will often give satisfactory results with aluminum and its alloys, best results will be obtained by following the methods described here.

Free-machining aluminum alloys are produced with machining characteristics that make them better suited than the other aluminum alloys for many of the operations performed by machine tools that are used for high production.

The following instructions are divided into two parts. The first part describes recommended tools and procedures for general machine-shop practice; the second part deals specifically with automatic screw-machine practice.

General Machine Practice

Tool Materials. Since their performance on aluminum is generally satisfactory, plain high-carbon tool steels are widely used for machining aluminum and most aluminum alloys. For quantity production work, however, high speed tool steels have replaced plain high-carbon tool steels to a large extent. Tools tipped with cemented tungsten carbide show marked superiority over both high-carbon and high speed tools. Cutting edges of carbide-tipped tools remain sharp much longer without regrinding, and they produce a better surface finish. In fact, tungsten carbide tools are necessary for best results with aluminum alloys of a high silicon content.

Tool Shapes in General. In the following description of tool shapes, a wide range of rake angles is indicated. In general, the larger rake angles are employed for finishing tools and for the aluminum alloys that are not free-cutting; this includes the softer materials, which require tools with exceptionally acute and keen cutting edges. On the other hand, rake angles in the lower range are used for roughing cuts and for machining the alloys that have free-cutting characteristics. Tools similar to those used for machining steel may often be employed successfully.

Top Rake. The top rake of the tools for cutting aluminum generally varies from 20 to 50 deg, depending on the type of tool used and the kind of stock to be machined. Finely finished surfaces may be produced with tools that have a top rake angle in the higher end of the range, but such tools can be used only in a machine that is sturdy and free from vibration, with no lost motion in its feeding mechanism. For some operations it may be necessary to use a top rake smaller than indicated by the above range, but a negative rake should never be used.

Side Rake. A side rake between 10 and 20 deg assists greatly in the cutting action of the tool, since it tends to produce a slicing action, enabling the tool to cut the metal more freely. Planer finishing tools have been ground with a side rake as great as 40 deg, in order to take full advantage of the good cutting characteristics of aluminum.

The cutting-tool angles previously described apply to the machining of aluminum in general. Although there are some tools to which they may not be adapted, these angles can produce the best results with many types of tools. Specific values for the different angles are governed by the work to be done and by the requirements of the machine in which the tool is used.

Clearance. The angle of clearance should be about 8 to 10 deg. This angle, plus the top rake angle indicated, leaves about 30 to [illegible] deg for the total included angle of the cutting edge of the tool.

Clearance is important and must be carried around the side of the tool that advances into the work material. If this clearance is too small, the side of the tool will rub against the stock and generate heat; if the clearance is too large, the tool may dig into the stock and chatter.

Tool Finish. It is essential that the cutting edges be keen, smooth, and free from grinding-wheel scratches, burrs or wire edges. Great emphasis must be given to this requirement, because success in machining aluminum and its alloys depends on the condition of the cutting edges to a large extent. Keen edges may be obtained by finish grinding on a fine abrasive wheel, then lapping, or hand stoning with a fine oilstone. Care must be taken so that neither the angles nor the contour of the cutting edge are appreciably modified during the finishing operations.

Fig. 3 Planer and shaper tool for machining aluminum
Fig. 4 Planer tool for roughing aluminum

Lathe Tools. Outside turning tools, for use in a lathe when machining aluminum and its alloys, may be of the form shown in Fig. 1. However, when tools of this kind are prepared from the usual tool-bit stock, they require considerable grinding in order to produce the desired shape, and it is sometimes difficult to maintain the values for the different angles when regrinding. A better tool is shown in Fig. 2. The bit of this tool is machined from annealed high-carbon or high speed steel and is then hardened. For sharpening readily, the bit is held by its shank in the chuck or collet of a tool-grinding machine or lathe, and the outside diameter is ground off until a keen edge is obtained. After each grinding, the tool should be stoned as mentioned previously. When using such a tool and such a resharpening procedure, it is comparatively easy to maintain the desired shape throughout the useful life of the tool. Also, this tool has proved more economical than those ground from square or rectangular tool-bit stock, and it possesses certain adjustable features. When the clamp screw of the tool-bit holder is loosened, the bit may be rotated to various positions and may thus be ad-

* Assistant Director of Research and Chief Engineer of Tests, Aluminum Company of America, New Kensington, Pa.

justed to different working conditions. Tools of this form may be used for both rough turning and finishing cuts; but where the same tool is employed for both, it should be restoned before being used as a finishing tool. With some modifications, either of these two forms of tools may be adapted for boring operations.

These tools, like most others suitable for machining aluminum and its alloys, tend to produce continuous chips, which are usually curled only a little when the tools are functioning properly. Where the character of the chips becomes a major problem, a reduction in the angles of top and side rake will tend to curl the chips more and break them up. The extent of adjustment that is possible while still obtaining the desired surface finish depends largely on the particular alloy that is being machined.

Parting tools for machining aluminum should have from 12 to 20-deg top rake and should be stoned so that the cutting edges are keen and smooth. With such tools the front clearance angle should be decreased to about 3 to 4 deg and light feeds should be used.

The angles of top rake and side rake recommended for outside turning tools should be interchanged for facing.

Planer and Shaper Tools. The tool shown in Fig. 2 can be readily adapted to planer and shaper work by using a holder, as shown in Fig. 3. Here again the tool may be used for both roughing and finishing work when machining aluminum; but a side cutting tool, as shown in Fig. 4, can be used to better advantage for heavier roughing cuts.

When aluminum is being finished in a planer or shaper, care must be used to prevent the tool from striking or rubbing on the finished surface during the return stroke; otherwise the work may be scratched and the thin edge of the tool broken.

Milling Cutters. In machining aluminum and its alloys, milling cutters, straddle mills, end mills and similar cutters work to best advantage if they are of the coarse-tooth spiral type that has a considerable amount of top rake on the cutting edges. In some instances milling cutters with nicked teeth help to decrease the chip size. Face-milling cutters should be designed so that the inserted teeth have appreciable top and side rake. The helical milling cutters, designed primarily for machining steel, work especially well with aluminum and its alloys if the cutting edges are provided with suitable top rake, that is, 10 to 20 deg. The same is true of staggered-tooth milling cutters.

Aluminum alloys may be milled at very high speeds. The speed at which metal can be removed is usually limited only by the equipment available. Milling operations have been satisfactorily performed on airplane spars of aluminum alloy at cutting speeds of 15,000 fpm or more in commercial production.

Threading Tools. Excellent threads may be chased even in the softest aluminum with an engine lathe using a single-pointed threading tool that has considerable top and side rake. Hand and machine taps will produce smooth and accurate threads in aluminum if they are of the spiral-flute, ground-thread type. Experience has shown that such taps should have preferably a right-hand spiral flute when intended for cutting a right-hand thread, and the spiral angle should be similar to that used in an ordinary twist drill. Taps that have a short spiral ground on the front end, such as the "gun" tap or spiral-pointed tap, will often work satisfactorily in aluminum where there is room for the chips to be forced ahead of the tap, and where the thread to be cut is not tapered; but taps of this type are not satisfactory for tapered threads or for use as bottom taps.

Thread chasers for self-opening die heads and collapsible taps should be ground with appreciable top and side rake. Certain types of these tools lend themselves more readily than others to modifications of cutting angles.

Twist Drills. Like all other cutting tools for aluminum, twist drills should have keen edges, and plenty of cutting compound should be used. The best drill for aluminum is one in which the flutes have a large spiral angle, that is, more twists per inch than the ordinary twist drill. Ordinary drills are suitable when the holes are not deep, less than six diameters. Twist drills with high spiral angles, as shown in Fig. 5, generally give better results for the softer alloys of aluminum. Polished flutes both improve the cutting action of the drill and assist greatly in removal of chips.

It may be necessary to withdraw the drill from the hole occasionally to dispose of the cuttings if the hole is deep in proportion to the diameter. A high speed and light feed are also helpful, especially for small drills. Examples of twist drills suitable for use on aluminum and its alloys are shown in Fig. 5.

Reamers. Reamers of the spiral-fluted type, like those generally used for machining steel, produce the best results on aluminum.

Saws. Since sawing is fundamentally a cutting operation, the principles that govern the shape of tools for machine cutting aluminum should be followed, as far as practicable, in the selection of saws for sawing aluminum.

Circular saws with chip-breaker teeth are better than the broad-tooth type. This type of saw has teeth so profiled that one cuts deep and the next cuts wide. Another

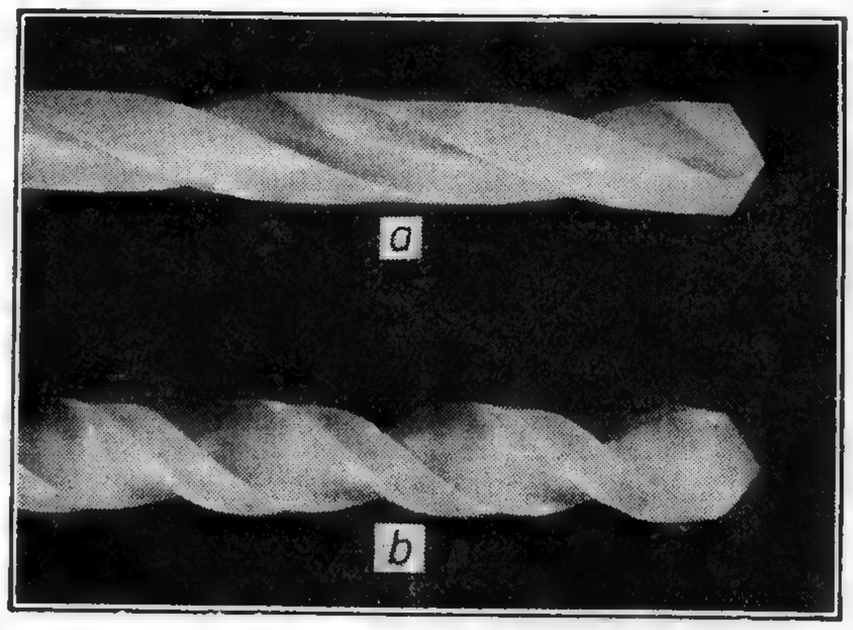

Fig. 5 Twist drills. (*a*) Double-fluted or standard twist drill, 24-deg spiral angle. (*b*) Special double-fluted twist drill, 47-deg spiral angle.

preferred type of saw blade has alternate side-rake teeth. The teeth are arranged alternately so that one cuts on one side and the next one on the opposite side of the saw cut. These teeth should have a side rake of about 15 deg.

For both types of blades, the top rake, or "hook", may vary up to about 45 deg. When such a large rake angle is employed, a tooth with a rather small included cutting angle results. Such teeth do not look very strong but experience indicates that, with other conditions correct, the teeth will serve longer without resharpening than when a small rake angle is employed. Obviously, with the use of a large rake angle, the sawing machine must be sturdy and free from vibration, the work piece must be securely clamped, and a positive feeding device must be provided. Where it is desired to feed the work material by hand, the saw teeth should have little top rake, if any; otherwise, the saw will enter the work too rapidly. Saw teeth for aluminum, however, should never have a negative rake.

It is important that proper clearances be provided on the sides of the teeth so that the teeth will not drag in the saw cut and cause the saw to overheat. Saws for cutting aluminum should have comparatively coarse teeth with curved gullets, free from sharp corners and burred edges, to prevent chips sticking.

Band saws of the high-speed metal-cutting type perform satisfactorily on aluminum. For light work, heavy-duty woodworking band saws may be used. Cutting speeds range from 2000 to 5000 fpm but higher speeds have been attained satisfactorily. For light work, band-saw blades made of spring-tempered steel are often used because the blades are readily resharpened. For heavy work, the flexible-back type of saw blade with hard teeth is preferred. Relatively coarse teeth—about 8 per in.— are preferable, although the number of teeth may be varied to suit sawing conditions. Relatively fine feeds are generally used to avoid large cuttings, but the feed will depend on the kind of work being done, especially on its size or shape.

A cutting lubricant or coolant is necessary for some classes of work, especially when sawing large heavy sections. Mineral-base lubricating oils, thinned with kerosene,

provide satisfactory lubrication when fed to the sides of the saw blade. Soluble-oil cutting compounds have also been found satisfactory. In some instances, an occasional application of paraffin wax or heavy grease will provide ample lubrication.

Hand hack-saw blades, of the "wavy-set" type, work especially well with aluminum.

Files. Files with single-cut coarse teeth, having considerable top rake, or "hook", work best on aluminum and its alloys. Such files, with deeply cut, curved teeth—about 10 per in.—are the best for general purposes. These files remove metal rapidly without loading the teeth, and produce a smooth finish. The long-angle lathe file is also excellent for filing aluminum, especially for fine work. Files of this type generally have a pitch of about 14 to 20 teeth per in. with single-cut teeth, cut at an angle of about 45 to 55 deg. This side rake angle permits the files to cut freely and helps to drive the cuttings from the teeth.

Ordinary files with single-cut fine teeth do not work well on aluminum, and those with double-cut teeth, whether fine or coarse, are no better, because the teeth load with cuttings.

Grinding Wheels. Good results are obtained with commercial grinding wheels of silicon carbide. The advice of the supplier should be obtained before selecting the proper grade of each commercial make of wheel.

Once a grinding wheel has been selected, three variables affect the quality of finish; namely, wheel speed, work speed, and grinding compound. A solution of soluble cutting oil and water serves well as a grinding compound. It is important that the fine grindings of aluminum be strained from the compound before reusing, in order to prevent deep scratches on the finished surface. Wheel speeds of about 6000 fpm have produced good results, but both wheel and work speeds can best be set by the experienced operator, according to his own judgment.

Rubber-bonded abrasive cutoff wheels can be used successfully for cutting the aluminum alloy products containing relatively large amounts of silicon, but such wheels tend to load when used in cutting the softer aluminum alloys. Cutoff wheels of this type should be operated at speeds of 9000 to 13,000 surface feet per minute and should be used with an abundant supply of cutting fluid, preferably a water-soluble oil, diluted with about 80 parts of water to one of oil.

Cutting Speeds and Feeds. Wide ranges may be used for cutting speeds and feeds in machining aluminum and aluminum alloys. The particular values for speed and feed usually depend on the character of the work, the type of tool, the lubricant, and the machine on which the work is done. Generally, aluminum can be machined to best advantage by using comparatively high speeds and fine to medium feeds. Ordinarily the finer the feed, the higher the speed should be. Extremely fine feeds should be avoided because they result in a rubbing rather than cutting action, and this is injurious to the tool.

A considerable amount of heat may be generated by tools that produce a tightly curled chip, and this may necessitate using a slower speed to prevent overheating the tool and the work material. When slow speeds and coarser feeds are used, a heavy cutting compound is preferred; this applies particularly to tapping operations. When the tools previously described are being used, the amount of metal removed from the stock in a given time may often be increased by an increase in the speed rather than in the feed.

When heavy, coarse-feed cuts are employed in engine lathe work, it is usual with aluminum, as with most other metals, for excessive friction to occur on the lathe centers because of the expansion of the metal with rise in temperature. Ball or roller bearing tailstock lathe centers help to decrease this trouble.

Cutting Lubricants. Some of the alloys of aluminum have been machined successfully without any lubricant or cutting compound, when the tools used have been of the form described; but in order to get the best results, some form of lubricant is desirable. Kerosene oil will often serve, but it works better ordinarily when mixed with pure lard oil. A satisfactory mixture for general purposes may be obtained by using equal parts of kerosene and lard oil. For heavy cuts and slow feeds, as in roughing work or tapping, pure lard oil has been found to give satisfactory results. For milling, sawing and drilling, the soluble cutting oils are satisfactory and more economical than the kerosene or kerosene and lard oil lubricants. Many of the proprietary cutting lubricants or compounds that are available commercially perform satisfactorily. A continuous and copious supply of lubricant should be fed to the tool in order to produce the best results.

Automatic Screw-Machine Practice

Stock. A number of aluminum alloys are commonly used for screw-machine stock. These may be divided into two general classes:

1 General-Purpose Alloys, 17 S-T4, 24 S-T4, 61 S-T6 and R 361-T. The choice between alloys 17 S-T4 and 24 S-T4 is based on mechanical properties; 24 S-T4 has higher strength. When these alloys are machined, the relatively long chips that are obtained sometimes, create a problem in chip disposal; but by the proper combination of feeds, speeds and tooling, the chips may be reduced considerably in size. The alloys 61 S-T6 and R 361-T are usually specified when the product is to be subject to severe conditions, requiring superior resistance to corrosion. Ordinarily the chips from these alloys are long and stringy and more difficult to handle.

2 Free-Machining Alloys for Use in Automatic Screw Machines. These alloys contain additions of lead and bismuth to impart free-machining characteristics. When the machining is done with tools that have little or no top rake, excellent finishes are produced and the chips are fine and broken. Currently, two alloys of this type are commercially available. Alloy 11 S has a nominal content of 5½% Cu and ½% each of Pb and Bi. This alloy is generally specified in the T3 temper, produced by cold working after a solution treatment. Alloy R 317, of more recent origin, has a composition similar to 17 S with small additions of lead and bismuth. It is usually supplied in the solution-treated and naturally aged temper.

Drills. Standard twist drills are ordinarily satisfactory for drilling holes that have a depth of 5 to 6 diam in aluminum alloys; but for deeper holes it is preferable to use straight-fluted drills or twist drills with less twist and with larger flutes, to provide greater chip clearance. Drills with a larger spiral angle, that is, more twists per inch, are preferred for the softer alloys. Generally, all drills used for aluminum should have narrow lands and large, smooth, highly polished flutes. These drills are usually ground with an included lip angle of 118 deg and a clearance angle of 12 to 20 deg. Sometimes a greater included angle is used so as to produce a narrow chip that will pass up the flutes more readily. Grinding the drill web thinner produces advantages as in drilling other metals. When a deeper hole is required, the drill must be withdrawn a sufficient number of times for removal of chips and proper application of cutting compound. It is usually safe practice to drill to a depth four times the drill diameter on the first entrance, 1½ to 2 diam on the second entrance, ¾ to 1 diam on the third entrance, and ½ to 1 diam on subsequent entrances.

Form and Cutoff Tools. Form and cutoff tools used in machining the free-machining alloys usually require ■ top rake from zero to 3 deg; for the other aluminum alloys better results will be obtained by using a top rake from 5 to 15 deg—the softer the alloy, the greater the top rake used. These larger rakes may be applied locally on the face of form tools for work involving large differences in diameter. In most instances a side clearance of ½ deg will aid in producing a smooth finish. Front clearance angles are determined by the design of the screw machine and the tools; the angles generally used in screw-machine practice are satisfactory for the aluminum alloys.

When used without support for the work material, the side pressure of the form-cutting tool will spring the stock and break it off, if the ratio of the formed length to the smallest diameter is too great. The limit for this ratio is 2½ for 17 S-T4 and 24 S-T4 and 2¼ for the other alloys. A front angle of 22 deg on a cutoff tool will usually reduce the cutoff burr to a minimum.

Box Tools. Holders for box tools are designed usually so that the tool is set with a clearance angle of 8 deg, but for some roughing tools this angle may be greater. The cutting face of the tool should be ground so that the bottom edge of the blade is parallel with the axis of the work piece. The cutting edge may be ground square with the tool shank, or with a slight angle, depending on whether or not a square shoulder is necessary on the work piece. For alloys other than the free-machining ones, a small groove or "hook" is ground just behind the cutting edge in order to produce a thin cutting edge and to provide considerable rake. This makes the tool cut more freely and forms the chips into helical coils that are guided out of the holder and away from the work. For long heavy cuts, the feeding cams may be notched with care to provide an interrupted feed to break the cuttings.

Threading Tools. Taps with "hook" as supplied by the maker may be used, but it is important that they be of the ground-thread type, with smoothly polished flutes to allow freer exit of the chips. Best results are obtained when the taps are provided with rakes from 10 to 15 deg, and with a clearance on the chamfer of about 3 to 5 deg. Thread chasers should be tapered or chamfered at least for two threads at the leading end of the tool so that they will start more easily.

Surface Speed of Stock. In general, aluminum alloys can be machined at the maximum spindle speed available in all standard types of automatic screw machines for turning, drilling, forming and cutting off. When tools that have cemented carbide tips have been used, aluminum alloys have been machined at 1000 fpm of stock surface, with no indication that such speed is excessive. How much this rate can be exceeded has not been determined. For threading and tapping operations, each type of machine has a suitable speed that is considered good practice for machining aluminum as well as all other materials. This speed is approximately one-third of that used for other operations.

The lighter weight of aluminum, about one-third that of other commonly used metals, is an advantage when high spindle speeds are employed. The lower inertia of aluminum causes less wear on the spindles, belts and motors, especially when quick changes in speed are involved.

Tool Feeds. Tool feeds vary with cutting conditions, as well as with requirements of tolerance and finish. Overlapping operations and the condition of the machine may require lower feeds than normal. The feeds shown in Table I are approximate and may need to be altered, depending on specific conditions. Generally, feeds approximately 15% higher than those given in Table I for aluminum alloys may be used for the free-machining alloys.

Table I. Approximate Feeds for Standard Tools in Machining Aluminum Alloys

Tool	Cut Width or Depth, in.	Diameter of Hole, in.	Feed per Revolution, in.
Box Tools, One chip finishing	1/32	.....	0.012
	1/16	.....	0.010

	0.009 to 0.012	1/8 and more	0.010

Cutting Compounds. Cutting compounds that are used for other metals are generally suitable for the aluminum alloys. A number of good commercial cutting oils, prepared especially for machining aluminum, give satisfactory results. Usually a light mineral oil is employed, with about 5% of fatty additions and with a viscosity from 45 to 55 Saybolt sec at 100 F. It is desirable to have a flash point higher than 260 F. As with all metals, it is essential that an ample supply of cutting oil be provided. A large volume flowing over the tools is more desirable than a high-pressure stream.

Finishes for Aluminum Alloys

By Junius D. Edwards*

ALUMINUM is a bright, silvery, corrosion-resistant metal which, for many applications, needs no special finishing by the user. Aluminum sheet, for example, can be purchased with a bright smooth surface or with "mill finish" of intermediate brightness. Aluminum extrusions are frequently employed just as they come from the die. Aluminum castings are generally used without any special surface finish except for necessary grinding and machining operations. There is, however, a wide variety of finishes that can be applied to aluminum for purposes of decoration and protection. These range from well-known mechanical procedures, such as polishing, scratch-brushing and sandblasting, to such unique finishes as anodic coating and electrobrightening.

Mechanical Finishes. Mechanical finishing operations are generally employed to remove appreciable amounts of metal and produce a uniform surface finish.[1] This finish may vary in smoothness from that left by grinding and sandblasting, to the high luster produced by polishing, buffing and coloring with a suitable abrasive, on wheel, disk or belt. In this way finishes are produced ranging from a highly diffusing surface to a mirrorlike surface. Sandblasting produces surfaces of varying degrees of roughness, depending on the fineness of the abrasive and the amount of pressure employed. This method is more commonly used for castings, since there is a strong tendency to warp sheet by blasting. However, with fine abrasive, a light dust blast applied to sheet can provide an attractive finish, particularly when used in combination with high-lighted areas. These mechanical finishing operations will not be described in detail, since they are much the same as for finishing other metals.*

Mechanical finishes do not, in themselves, add anything in the way of surface protection. Frequently, however, mechanical finishes are used as surface preparation for a final finishing operation, such as electrobrightening or anodic coating. In this way, a combination of surface preparation methods and other finishing techniques will give a product luster, texture, or color, combining serviceability and attractive appearance.

Cleaning and Etching. Cleaning is sometimes necessary for the removal of oil, grease, or other contaminants on the surface of aluminum. For production work, vapor degreasing or a dip into a solvent may be called for, or a simple chemical cleaning solution may be employed. Many alkaline solutions that will remove grease and oil from aluminum are not satisfactory for most cleaning purposes be-

* Assistant Director of Research, Aluminum Research Laboratories, New Kensington, Pa.

* *See* "Blast Cleaning of Metals", page 300 in this Handbook.

cause they either etch or discolor the surface. However, safe cleaners are available which can be used on aluminum without etching or discoloration.[3] A safe cleaner can be made from sodium carbonate and phosphates of sodium, suitably inhibited with sodium silicate to eliminate the etching action. Such a cleaner is usually employed at temperatures of about 140 to 180 F in order to accelerate the cleaning action. This treatment is followed by rinsing and drying. Excellent cleaning solutions are available.

Aluminum articles can be given a bright, frosted finish by a dip in a hot solution of caustic soda, followed by a dip in strong nitric acid. The caustic soda solution is used in concentrations from about 5 to 15%, and at room temperature or at temperatures of about 160 to 180 F for a period of about a minute. After this treatment the metal is rinsed in clear cold water. The next step in the procedure is immersion in strong nitric acid (1 part water, 1 part concentrated HNO_3, 38 Bé). Then the metal is given a final rinse in water and rapidly dried. The treatment with nitric acid neutralizes any traces of alkali and brightens the surface. When alloys containing substantial amounts of silicon are to be treated, it is necessary to add hydrofluoric acid to the nitric acid; one part of concentrated hydrofluoric acid (48% HF) to eight parts of concentrated nitric acid is a good proportion to use. After treatment in the caustic soda solution, the article is dipped into the cold nitric-hydrofluoric acid mixture for 15 to 30 sec, then again washed in water and dried.

Aluminum articles can be given a smooth, bright finish by immersion in a solution containing about 2% by volume of concentrated hydrofluoric acid and 10% by volume of concentrated nitric acid. The solution must not become too warm.

For removing films and stains from annealing and heat treating operations, a dip into a solution containing about 10% sulfuric acid and 3% chromic acid, operated at 160 F, will be found effective. This treatment removes far less metal than does caustic dipping, and it leaves the article (such as a pressing, forging or extrusion) with a bright attractive finish.

Anodic Oxide Coating of Aluminum. One of the outstanding characteristics of aluminum is the high protection afforded by the very thin, invisible film of aluminum oxide naturally formed on the surface. Oxide films of substantial thickness can also be formed by anodic treatment in certain electrolytes, usually of an acid character.[3] These anodic coatings are minutely porous, and during anodic treatment the current carried by the electrolyte in the pores converts the base metal into aluminum oxide. During formation, therefore, the oxide grows into the metal, leaving the first-formed oxide on the surface. The oxide coating is integral with the aluminum and this, in large part, accounts for its excellent adhesion to the base metal. The coatings are essentially amorphous aluminum oxide, but may contain sulfate or other substances adsorbed from the electrolyte.

The first anodic coating procedure to receive wide application was developed by Bengough and Stuart and employs a 3% solution of chromic acid as the electrolyte, at a temperature of about 100 F. In operation the voltage is raised from zero to 40 at the rate of about 8 v per min, and is maintained at full voltage for 30 to 60 min. This gives a current density of about 1 to 3 amp per sq ft. These coatings are relatively thin (0.00005 to 0.0001 in.) and their principal use has been as a base for paint on aluminum aircraft parts. The usual color is grayish green, resulting from the presence of reduced (trivalent) chromium in the coating.

The Alumilite process[1] presents a variety of procedures for producing anodic coatings on aluminum and adapting them to practical service conditions by sealing and coloring treatments. The electrolyte which has received the widest acceptance is an aqueous solution containing about 15 to 25% sulfuric acid. This electrolyte has the advantage of yielding clear transparent coatings on pure aluminum, and translucent or opaque coatings on metal of lower purity, such as 2 S sheet (99% min Al). During anodic treatment of aluminum alloys, the behavior of alloying constituents is important in determining the characteristics of the coating. Certain constituents may be anodically dissolved and removed from the coating, whereas others, unattacked or partially oxidized, may remain in the coating as occlusions. Removal of constituents or inclusions from the oxide during anodic treatment, may therefore affect the continuity and protective power, as well as the appearance of the coating. The thickness of the coating is primarily a function of the current employed (ampere-minutes) and is under control of the operator. Commercial coatings are usually produced in the thickness range of 0.0001 to 0.0008 in. The oxide forming the coating is intrinsically hard and the resistance of the coating to wear will usually increase with thickness.

A unique characteristic of these coatings is their submicroscopic porosity. These pores, which require the electron microscope for viewing, will admit solutions and thus provide a variety of ways in which the characteristics of the coating may be altered. If the pores of the coating are impregnated with a solution of a dye of suitable type, the dye becomes firmly adsorbed on the coating and colors it throughout the depth. A great variety of colors can be produced in this way and the dye-colored coatings have a semimetallic luster that is very attractive. These dye-colored coatings are not proof against fading in sunlight, although they are virtually permanent indoors. However, they are satisfactory for many outdoor applications where several years' service is sufficient. The pores are too small to admit solid particles, but after the coating is impregnated with two reacting solutions in turn (a solution of cobalt acetate, for example, and subsequently a solution of ammonium sulfide), a mineral pigment such as black cobalt sulfide can be precipitated within the pores. A variety of mineral pigment colors is available. When applied under proper conditions, they are very serviceable in outdoor applications.

For most purposes, however, the uncolored coating is desired, and for most applications it is necessary to make the coating nonadsorptive to prevent accidental staining. This is accomplished by a sealing operation. Sealing without coloration can be accomplished by treating the coating with hot water for a period of 10 to 30 min. Sealed coatings on cafeteria trays, for example, will not stain from contact with coffee and other colored fluids and foods. The coating may not only be sealed but may also be impregnated with a corrosion inhibitor by treatment with chromate solutions. The chromate, adsorbed in the coating, is effective in protecting against attack in many environments. Coatings sealed in this way form an excellent base for paint and have been used extensively in protecting aluminum alloy aircraft parts.

The Alumilite process provides other coating electrolytes, notably solutions containing both sulfuric and oxalic acids, to give especially hard and dense coatings for applications requiring these characteristics. Oxalic acid alone has also found application as an electrolyte.

When anodically coated articles are dusty or dirty, they can usually be cleaned by wiping with a damp cloth or with mild soap and water. Care should be taken, in the selection of a chemical cleaner, for many alkaline cleaners attack and dissolve the coating; however, safe cleaners are readily available.

Electrobrightening or Electropolishing. Electrobrightening or electropolishing of aluminum can be accomplished by suitable anodic treatment. The process most extensively used and one which introduced commercially electrobrightening or electropolishing of aluminum, is the Alzak process.[4] When a buffed aluminum surface is made anode in fluoboric acid electrolyte, a thin surface film of metal is removed with such uniformity that the specularity of the surface is not appreciably disturbed. As soon as embedded polishing materials and other dirt have been removed in this manner, the surface is ready for anodic coating in sulfuric acid electrolyte. If the aluminum is free from certain alloying constituents, a protective film of clear, transparent aluminum oxide is formed. The electrobrightened surface may have a reflectivity as high as 90%. The reflectivity will be reduced somewhat by the oxide coating, and the reduction is a function of the thickness of the coating. However, specular aluminum reflectors with a reflectivity of 80 to 85% can be made with oxide films as thick as 0.0004 in. The electrobrightening procedure may be employed in decorative finishes to provide an interesting contrast in luster and texture between brightened and dust-blasted surfaces.

Oxide Coating by Chemical Treatment. Artificial oxide coatings can be applied to aluminum by chemical treatment as well as by electrolytic treatment. So far it has not been possible, however, to make these coatings as hard and resistant to abrasion as those made by suitable anodic procedures. For many purposes, however, the "chemical" coatings are adequate and can be produced at lower cost.

One solution for the production of such a coating is made with sodium carbonate and potassium or sodium dichromate. When the proper ratio is maintained between carbonate and dichromate, the hot solution in contact with aluminum produces a grayish green coating, the thickness of which depends on the duration of treatment. The principal applications for this coating have been in the treatment of small parts, and in the surface treatment of aluminum articles that are to be painted subsequently. In these applications the coatings known as Alrok coatings[1] are usually impregnated with dichromate solution to lend added protection.

A substantial number of other coatings produced by chemical treatment are described in technical articles and patents. Several excellent proprietary procedures are available for the surface coating of aluminum alloys before painting. Other processes yield colored coatings of decorative value. With coatings of this type for use without paint or enamel, one problem is how to secure adequate thickness and wear resistance.

Electroplating. The electroplating of other metals upon aluminum has now received commercial acceptance. This has become possible through the development of special methods for treating the aluminum surface to leave it in satisfactory condition for subsequent plating by conventional methods.

An oxide film in itself is not a deterrent to successful electroplating of aluminum; several available methods of anodic treatment produce a porous oxide coating of appreciable thickness to which electroplates show good adhesion. Several etching methods also produce a satisfactory surface for electroplating. However, the method most generally applicable comprises immersion of the aluminum article in a solution of sodium zincate of controlled composition. A dark-colored film that contains zinc is deposited in a short time. After this treatment, other metals can be successfully electrodeposited. A commonly used finish comprises successive deposits of copper, nickel and chromium, although other metals may be applied over the copper. Brass, iron, silver or chromium can also be applied directly over the zinc immersion coating.

Silver plate is applied to electrical equipment to decrease contact resistance or to improve surface conductivity. Brass plate facilitates the vulcanization of rubber to the surface. Copper coatings are sometimes employed to permit assembly by soft soldering. Heavy chromium deposits are used to reduce friction and increase wear resistance. Chromium deposits applied directly to aluminum provide increased resistance in an alkaline environment. Zinc is used in threaded parts to prevent seizing where the presence of organic lubricants is undesirable. Tin may be employed to reduce friction between sliding surfaces.

Because of the unfavorable solution potential of aluminum with respect to certain electrodeposits, aluminum parts plated with such metals as copper or nickel should not be exposed to a corrosive environment unless the electroplate is heavy enough to be impervious (about 0.0015 in. of nickel). The thickness of electroplate on aluminum should therefore be about that used in plating on iron or zinc.

Painting of Aluminum. Paints generally show good adhesion to the natural oxide film on aluminum.[5] For severe service conditions, such as involve frequent wetting and drying, better adhesion can be secured by special treatment of the surface to increase its passivity. Of course it is necessary, as with other metals, to remove oil and grease films prior to painting; this can be done by wiping with cloths moist with solvent or by vapor degreasing.* A combined degreasing and chemical treatment is provided by a solution comprising phosphoric acid and suitable grease solvents, such as the alcohols (U. S. Army Corps of Engineers' Specification T1184-D). The grease solvent permits the phosphoric acid to wet the aluminum surface and, by reaction, a film of inert aluminum phosphate is formed in a few minutes. The surface is then thoroughly washed with clean water and dried, after which it is ready for painting. As indicated in other sections of this article, various chemical and electrolytic treatments also provide good surface preparation for painting.

The use of zinc chromate (zinc yellow) pigment in priming paints for aluminum has received general acceptance. This pigment is not pure zinc chromate but is a double compound containing potassium chromate of limited solubility. No doubt this sparingly soluble chromate exerts a protective action when water vapor penetrates the film. The priming coat usually employs a synthetic resin vehicle, offering high resistance to penetration by moisture.

Aluminum paint is an excellent top coat for most applications because of its low permeability to moisture; however, other color-pigmented coats can be applied if desired. Synthetic resin vehicles of high resistance to moisture and suitable distensibility should be employed where the service conditions demand protection as a primary consideration. Clear lacquers of the methacrylate resin or cellulose acetobutyrate type are recommended where a transparent protective finish is desired. Thick coatings of bituminous paint are quite effective for protecting aluminum that is to remain in contact with soil, cement or plaster.

The Resistance of Aluminum Alloys to Corrosion

By E. H. Dix, Jr.* and R. H. Brown*

THE successful use of aluminum and aluminum alloys in many fields depends on the ability of these products to resist a variety of corrosive environments. For this reason it is important that the behavior of aluminum alloys in regard to corrosion should be well understood and that the limitations of the alloys under certain conditions in service should be recognized. Aluminum electric transmission lines and aluminum cooking utensils are perhaps the earliest applications that have stood the test of time. Aluminum has also become established as an architectural material; aluminum roofs more than 40 years old are known to be giving satisfactory service at present.

The high-strength aluminum alloys, most of which contain copper as the principal alloying element, have a lower order of resistance to corrosion than that of aluminum or the aluminum alloys used where strength is not the principal consideration. However, improvements in manufacture, especially heat treatment, and the development of satisfactory methods of protection have resulted in the successful use of these high-strength alloys under many corrosive conditions. For example, when the first aluminum airplanes were built after World War I, considerable corrosion of the thin, high-strength aluminum-copper alloy sheet was experienced. In contrast, the high-strength

* Assistant Director of Research, Aluminum Company of America, New Kensington, Pa.

aluminum alloys (millions of pounds) used in the aircraft of World War II were almost free from difficulties caused by corrosion, even though the planes operated with little protective care.

Corrosion Behavior of Aluminum and Its Alloys. *Protection Afforded by Oxide Film.* Although aluminum is an active metal, it behaves as a very stable one because it is covered with a thin oxide film that is highly resistant and protective. Aluminum owes its commercial existence to this film. If the surface of aluminum is scraped sufficiently to remove the oxide film, in many environments a new film begins to form immediately.[1] Thicker, more protective and decorative oxide coatings can be produced by chemical and electrolytic treatments.[2,*] In conditions under which the protective film does not re-form readily, aluminum should be protected adequately or not used at all. Among such conditions are contact with strongly acid or alkaline solutions and contact with constantly moist corrosive materials that prevent free and uniform access of oxygen to the aluminum surface.

Contacts Between Dissimilar Metals. The highly anodic electrode potential causes aluminum to be dissolved sacrificially when in contact with most other metals in corrosive environments.[3] The electrode potentials of a number of aluminum alloys and some other metals[1,4] are given in Table I. Not only must the direct metallic contact with a more cathodic metal be avoided but also corrosion products of these metals must be kept from the surface of aluminum;[1] for example, copper picked up from copper or brass plumbing will plate out on aluminum cooking utensils and cause pitting unless removed by periodic abrasive cleaning. Rain splashing from copper or copper alloy surfaces onto an aluminum surface will also cause corrosion; for example,

copper or bronze screens will cause pitting of aluminum window frames in all except very mild atmospheres. Stainless steel, in spite of its cathodic electrode potential, causes relatively slight electrolytic attack on aluminum alloys when in contact with them,[5] since the flow of current is limited by polarization. Zinc and cadmium are sufficiently close to aluminum alloys in electrode potential to be used successfully with them.

Electrode Potentials of Alloy Constituents. Because of the electrochemical nature of most corrosion processes, relationships among electrode potentials are important also in determining the resistance to corrosion of aluminum alloyed with other metals.[3] Table II gives the electrode potentials of aluminum and of some of the constituents found in the common aluminum alloys.

The impurities that occur in commercially pure aluminum—iron, silicon and copper—are cathodic to aluminum. However, the aluminum-iron constituent is ordinarily the only cathodic constituent present, because copper is always well within the limits of solid solubility and silicon is usually in solid solution either in the aluminum-iron constituent or in aluminum itself. The particles of the aluminum-iron or aluminum-iron-silicon constituent form cathodic points that weaken the oxide film besides promoting electrochemical attack; hence the resistance to corrosion of high-purity aluminum with a minimum aluminum content of 99.95% is higher—under some conditions markedly higher—than the resistance of commercially pure aluminum.

It will be observed that manganese and aluminum form a compound that has almost the same electrode potential as aluminum. This is true also of the constituent formed when magnesium and silicon are added in the ratio of the compound Mg_2Si. These alloying elements produce alloys that are comparable with commercially pure aluminum in their resistance to corrosion. Chromium and manganese behave similarly with respect to corrosion, but chromium is employed only as a minor alloying element, particularly valuable in improving the resistance to stress corrosion of several types of aluminum alloys.* Magnesium and silicon in solid solution in the ratio of the compound Mg_2Si do not affect the electrode potential of the alloy; however, most other alloying elements forming a solid solution with aluminum do alter its electrode potential. Magnesium and zinc, either individually or together, in solid solution in aluminum make the potential more anodic, whereas copper makes it more cathodic. Silicon, although cathodic to aluminum, has relatively little effect on its electrode potential when in solid solution, because of relatively low solid solubility. Both the aluminum-magnesium and the aluminum-silicon alloys have good resistance to corrosion. When magnesium is alloyed with aluminum in amounts that remain in solid solution under conditions of commercial manufacture, the alloys are as resistant as commercially pure aluminum and are even more resistant to salt water and some alkaline solutions, such as those of sodium carbonate.[6,7] The aluminum-magnesium constituent formed by magnesium in excess of the solid solubility, is anodic to the aluminum-magnesium solid solution and hence, under some conditions of thermal treatment, lowers the resistance to corrosion of the alloy.

Nickel and aluminum form a strongly cathodic constituent that usually has an adverse effect on the resistance of aluminum alloys to corrosion. However, nickel is employed primarily in alloys that require high strength and hardness at elevated temperatures, and in such application the resistance of the alloy to corrosion is of little

* *See* "Finishes for Aluminum Alloys", page 789.

* *See* "Stress Corrosion of Metals", page 227.

importance. Tin, bismuth and lead are also cathodic to aluminum. The latter two elements are used in free-cutting alloys of the aluminum-copper type and may lower the resistance to corrosion of these alloys under some conditions of exposure. Tin is an important element in aluminum alloys that are used for bearings. Although, under some corrosive conditions, these alloys may resist corrosion less effectively than certain other aluminum alloys, the aluminum alloys that are used for bearings resist remarkably well the action of the breakdown products of lubricating oils and are superior in this respect to most bearing materials. The aluminum-titanium constituent, although cathodic to aluminum, has not been found to have a detrimental effect on resistance to corrosion.

Copper in solid solution changes the electrode potential markedly in a cathodic direction. The aluminum-copper constituent is even more strongly cathodic to aluminum;[8] hence copper in excess of about ¼% may have an adverse effect on the resistance of aluminum alloys to corrosion. An exception to this generalization occurs in several alloys in which copper in combination with other elements is beneficial.

Effect of Heat Treatment. The microstructural condition produced as a result of thermal treatment has an important influence on the resistance to corrosion of aluminum-copper alloys.[9] The aluminum-copper solid solution produced by a solution heat treatment and rapid quench has the highest resistance to corrosion. Aging at room temperature, which causes precipitation of minute particles of submicroscopic size in uniform dispersion, does not lower measurably the resistance to corrosion. However, reheating or a slow quenching rate that produces localized precipitate surrounded by areas of depleted solid solution, results in a pronounced decrease in resistance to corrosion. The areas of depleted solid solution are anodic both to the remaining areas of solid solution and to the precipitated particles and, hence, in a corrosive environment, are dissolved out rapidly, resulting in so-called "intergranular" corrosion. Resistance to corrosion is restored to a point where it equals that of the rapidly quenched solid solution by further aging at elevated temperatures or a combination of controlled quenching and artificial aging, which causes more general precipitation and so equalizes the potential in the various solid solution zones. For a more detailed discussion of this subject, the reader may refer to the article "Stress Corrosion of Metals", on page 227 in this Handbook.

In the aluminum-magnesium-silicon alloys that contain magnesium and silicon in the ratio of the compound Mg_2Si, the resistance to corrosion is not affected by precipitation, because in this ratio the electrode potential is the same, whether these elements are in or out of solid solution.

Alclad Products. Relationships between electrode potentials are used to advantage in alclad products,[10,11] in which an aluminum alloy core is covered with a thin surface layer or layers of aluminum or of an aluminum alloy resistant to corrosion, both anodic to the core. Thus when these products are used in a corrosive environment, not only do the surface layers protect the core, by virtue of their high resistance to corrosion, but they also protect electrolytically areas of the core exposed at the edges by cutting, or elsewhere by abrasion or corrosive attack. This electrolytic protection is important in the high-strength alclad products because it preserves the initial strength of the product even under severely corrosive conditions. Alclad sheet is especially resistant to perforation since, as long as appreciable areas of coating remain, pitting does not progress beyond the interface between the coating and the core, but spreads out slowly instead, producing a shallow area of attack. This action is particularly desirable in relatively thin sheet because it permits exposure for a long period of time without risk of perforation.

Aluminum and alloys of the magnesium silicide type are suitable for coatings on the aluminum-copper high-strength alloys in which the copper remaining in solid solution, after heat treatment, makes the core so cathodic that the coating is anodic to the core. For alloy cores having about the same electrode potential as aluminum (such as 3 S, 4 S, 61 S-T6 and 75 S-T6) or having a potential even higher than that of aluminum (as in 56 S), a coating that contains 1% Zn or more may be used in order to achieve the desired electrolytic protection.

The Relative Resistance to Corrosion of Commercial Aluminum Alloys. The properties and characteristics, other than resistance to corrosion, of most of the alloys discussed in this section are described on pages 810 to 840. Tables III and IV show nominal compositions.

High-Purity Aluminum. For the reasons previously stated, high-purity aluminum, under most conditions of exposure, surpasses the other forms of aluminum in resistance to corrosion. This resistance increases with increase in purity.

Commercial Aluminum. Aluminum of commercial purity also has a high resistance to corrosion, which is comparable, except in special instances, with that of the most resistant alloys. The wrought product 2 S is used for a large number of miscellaneous applications where good resistance to corrosion is required, as well as for such products as cooking utensils and equipment for the handling of chemical solutions.

Aluminum-Manganese Alloys. The wrought aluminum-manganese alloy 3S possesses a general resistance to corrosion comparable with that of 2S. Among the applications illustrating the resistance of 3S to corrosion are roofing and siding, cooking utensils, and tanks and tubing to handle water and a number of chemicals. A cast aluminum-manganese alloy, 406, because of good resistance to corrosion, is used for pipe fittings in connection with 3S or Alclad 3S pipe.

Aluminum-Magnesium Alloys. All the aluminum-magnesium alloys possess a high order of resistance to corrosion. The alloy 52S resists atmospheric weathering very well, and because of exceptional resistance to sea water, has been used rather extensively for marine applications. This alloy has been used considerably in equipment for the chemical industry and is used also for heavy-duty cooking utensils and the bulk processing of foods. Another alloy, of higher magnesium content, 56S, is used for corrosion-resistant wire products.

The casting alloy 214 is used for ornamental castings where a white color is desired, for cooking utensils, for the bulk processing of foods, for a number of fittings for equipment in the chemical industry, and also for marine applications. A related alloy, B214, which contains some silicon as an alloying element, is used for similar applications and especially for pipe fittings for marine use. The die-casting alloy 218 resists corrosion and tarnish very well, and for that reason is used for hardware fittings and for various parts in aircraft and ships. The sand-casting alloy 220 is used for aircraft and marine castings and for frames of railroad cars.

Aluminum-Manganese-Magnesium Alloys. The wrought aluminum-manganese-magnesium alloy 4S is used in many of the same applications as 3S or 52S, because the resistance to corrosion of these alloys is similar.

Aluminum-Silicon Alloys. The casting alloy 43 is able to resist both atmospheric weathering and a wide variety of waters, chemicals and food acids. Its uses under corrosive conditions include fittings in refrigerators, carburetor bodies, cooking utensils, architectural and ornamental parts, pipe fittings, marine fittings, and a wide variety of food-handling equipment. The die-casting alloys, 13 and 360, and the heat treatable alloy 356, are comparable with 43 in their resistance to corrosion. The alloy 356 is used for such applications as liquid-cooled engine cylinder blocks, pump parts, aircraft and marine fittings, and castings for the chemical industry. The heat treatable casting alloy, 355, because of its copper content, is somewhat less resistant to corrosion than alloy 356. However, it is used for a large number of aircraft parts, liquid-cooled cylinder heads for aircraft, impellers for superchargers, water jackets and fuel-pump bodies. Red X-8, an alloy of related composition, has found use in the same type of applications. The wrought alloy 32S, and the casting alloys A132 and Red X-13, which contain higher silicon than the alloys previously mentioned, compared favorably with them in resistance to corrosion.

Aluminum–Magnesium Silicide Alloys. The wrought aluminum–magnesium silicide alloys are important because their general resistance to corrosion is comparable with that of the wrought alloys that are not heat treatable (2S, 3S, 4S and 52S) and their strength after heat treatment is considerably higher. The resistance to corrosion of the wrought aluminum–magnesium silicide alloys is independent of temper. For many uses these alloys do not require paint as protection. The alloy 53S has been employed for structural purposes where a high degree of resistance to corrosion is required and, to a considerable extent, for equipment used in the handling and processing of chemicals and beverages. The alloy 61S is only slightly less resistant to corrosion than 53S and is satisfactory for structural applications under severe conditions of exposure. It is used also for processing and handling beverages and chemicals, except where the copper content is undesirable. Extruded parts made of 63S are widely used for architectural purposes. This alloy is comparable with 53S in resistance to corrosion and has a brighter color. The forging alloy A51S, which contains silicon in excess of the magnesium silicide ratio, has resistance to corrosion in the T4 temper comparable with that of 53S, but artificial aging to the T6 temper decreases this resistance. Nevertheless, resistance to corrosion of A51S-T6 is superior to the resistance of ■ number of other types of aluminum alloys of comparable strength.

Aluminum-Copper Alloys. The wrought aluminum alloys 17S-T4 and 24S-T4, which contain copper as the main alloying element, resist corrosion satisfactorily but are inferior in this respect to the alloys of the aluminum–magnesium silicide type, such as 53S and 61S. The resistance to corrosion of 17S-T4 and 24S-T4 is decreased by slow quenching from the solution heat treatment temperature, or by subsequent reheating. Thick sections of the alloy 24S in the artificially aged (T8) tempers have a resistance to corrosion comparable with that of similar sections of 24S-T4.[13] The wrought aluminum alloy 14S, which contains added silicon, is comparable in the T4 temper with 17S-T4 in resistance to corrosion. The commercially available products of 14S-T6 have the same order of resistance to corrosion as products of 24S-T4 that are similar in cross section. These aluminum-copper alloys have been widely used for aircraft construction and for general-purpose structures. In such applications they are always painted for protection. The forging alloy 25S has a lower order of resistance to corrosion than 17S-T4 and 24S-T4 but the millions of aircraft propeller blades made of this alloy have given satisfactory service in many climates. Because of their lead and bismuth contents, the free-cutting alloys 11S and R317 have a somewhat lower resistance to corrosion than 17S-T4, under some corrosive conditions. The alloy 11S is most resistant in the T3 temper.

The sand casting alloy 195 and the permanent mold alloy B195 (which also contains silicon as an alloying element) have good resistance to atmospheric weathering and are used for such parts as wheels and fittings for aircraft and fittings for railroad cars; but in general, protection against corrosion is recommended. The wrought alloy 18S, the casting alloy 142 (both of which contain nickel and magnesium in addition to copper) and the casting alloy 122, are possibly somewhat inferior to 195 in resistance to corrosion but are in the same general class. Except in cylinder heads for air-cooled engines, parts made of the latter alloys are seldom subjected to corrosive environments.

Aluminum-Copper-Silicon Alloys. With respect to resistance to corrosion, the alloys containing substantial amounts of both copper and silicon can be treated as a group. Their resistance to corrosion is comparable with that of the aluminum-copper alloys. The alloys 108, 113 and C113 contain copper in excess of silicon, whereas the alloys 85, Allcast, A108, and 380 contain silicon in excess of copper. They all resist atmospheric weathering fairly well, but for severely corrosive conditions paint is recommended as protection. As examples of their use, unprotected 108 is used for manifolds; A108, for ornamental grilles and reflectors; and C113, for agitators in washing-machines.

Aluminum-Zinc Alloys. Because of its anodic electrode potential, the aluminum-zinc alloy 72S is used as an alclad coating to protect electrolytically those alloy core compositions that have an electrode potential too anodic to be adequately protected by pure aluminum. The resistance to general corrosion of 72S is only slightly, if at all, inferior to that of 2S.

Aluminum-Zinc-Magnesium Alloys. The wrought alloy 75S is comparable with 24S-T4 in resistance to corrosion; hence, the same protective measures against corrosion are used. The alloy R303 can be classified in this group. The casting alloy 40E has good resistance to general corrosion.

Alclad Products. Alclad 17S-T4 and Alclad 24S-T4 sheet have been used extensively in aircraft construction for more than 15 years. As skin for the wings and fuselage, these alclad products resist atmospheric corrosion satisfactorily without paint or other protective measures. The alclad products currently available in the form of sheet and plate include Alclad 3S, Alclad 24S, Alclad 75S, Alclad 14S, and R301; in the form of tubing, Alclad 3S, with a coating on the inside surface only; and in the form of wire, Alclad 56S. Alclad 75S-T6, Alclad 14S-T4, and R301-W are comparable with Alclad 24S-T4 in resistance to

corrosion. The difference in electrode potential between coating and core of Alclad 14S-T6 and R301-T is smaller than in Alclad 14S-T4 or R301-W; consequently their resistance to corrosion is somewhat lower. Alclad 3S is used primarily where resistance to penetration under corrosive conditions is the chief consideration. Alclad 56S is used extensively for wire that is to be made into insect screen cloth.

Resistance to Atmospheric Exposure. In situations where air has free access to their surfaces, aluminum and the more corrosion-resistant aluminum alloys exhibit satisfactory weathering characteristics in rural, urban, industrial and seacoast atmospheres. In comparison with that of other metals, the resistance to industrial atmospheres is outstanding. The corrosion-resistant aluminum alloys also withstand seacoast atmospheres satisfactorily.[5]

The importance of the protective oxide film on the resistance of aluminum to corrosive environments, was discussed in the introduction to this article. When aluminum is exposed to the weather, moisture and dirt that collect on the surface cause breakdown of the weak spots in the protective oxide film, and tiny pits are formed. The metal from these pits is converted to a hydrated aluminum oxide, thus forming a thicker coating, which greatly retards further attack. At this stage of weathering, the aluminum surface presents a somewhat nonuniform, speckled appearance. In the course of several months or a year, depending on the atmospheric conditions, the appearance of the surface becomes more uniform; the color depends on the amount of dirt in the atmosphere. In industrial regions the color becomes ■ slate gray, whereas in clean, seacoast atmospheres the surface takes on more of an etched, whitish appearance. In dry, clean locations, such as Phoenix, Ariz., the bright metallic sheen remains almost untarnished for a period of years. Sheltered areas of the metal are likely to develop a thicker, rougher oxide coating than surfaces that are frequently washed with rain. When the appearance of the weathered surface is objectionable, the bright metallic appearance may be preserved by simple periodic cleaning with an abrasive cleaner, such as Bon Ami or steel wool and soap.

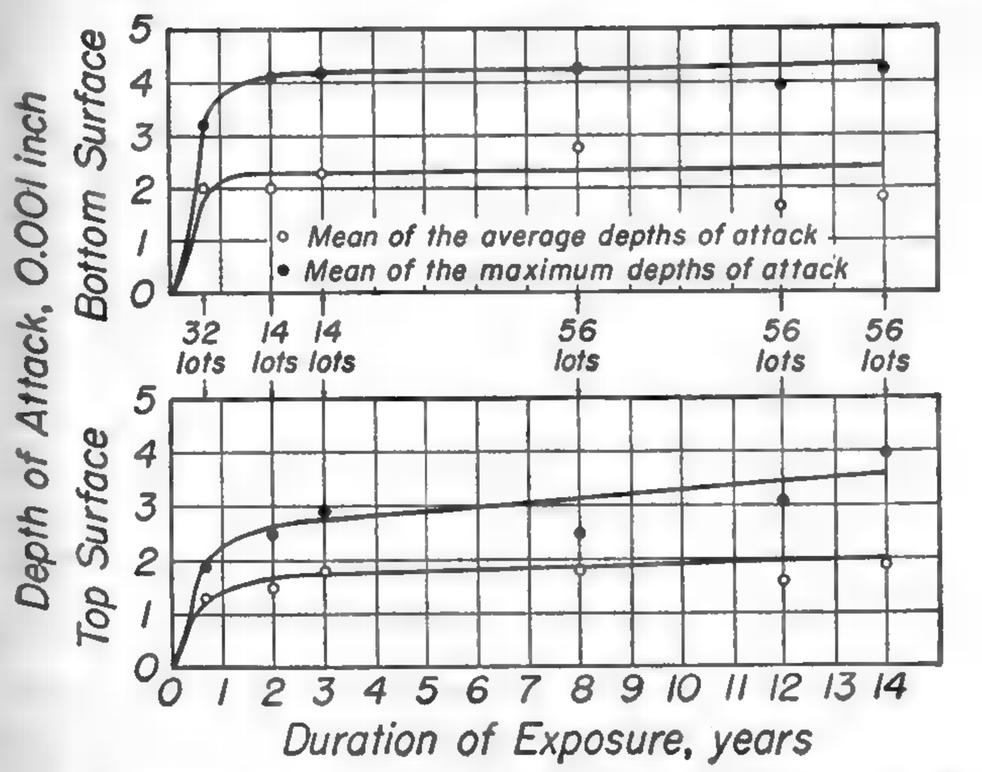

Fig. 1 Rates of corrosion of aluminum alloys during exposure to the industrial atmosphere of New Kensington, Pa. Alloys tested were 2S, 3S, 4S, 43S, 51S and Al plus 2 to 6% Mg. Specimens were in the form of sheet 0.064 in. thick. Panels were exposed at 45 deg, facing south. Fifty-six lots were tested.

The curves of Fig. 1 show the rate of attack by corrosion on the surfaces of a number of aluminum alloys exposed to an industrial atmosphere. The self-stopping action of this type of attack with free circulation of air, is well illustrated. Pitting to the depth of 0.002 to 0.003 in. occurs in the first year or so. After this period the protective oxide coating has become sufficiently thick for the rate of attack to progress much more slowly, and even after 10 to 20 years the depth of attack is not much more than about twice that in the initial period. In seacoast atmospheres, pitting may be more rapid in some locations, but this attack also is self-stopping and the maximum depth of pitting after a number of years is not more than twice that found in industrial atmospheres.[13]

The weathering of aluminum under conditions that permit free access of air to its surface has been described. Under conditions of exposure that prevent free circulation of air against the surface of the aluminum, the corrosion behavior is quite different; for example, where a constantly moist absorbent material is in contact with an aluminum surface. Even if the material is relatively inert, oxygen concentration cells are set up that accelerate the corrosion of aluminum.[14] The corrosion product that forms is mostly an aluminum hydroxide, which remains wet and gelatinous and thus offers little protection from further attack. However, occasional drying does permit the formation of a protective film that retards further attack temporarily. The influence of a moist absorbent material as just described is sometimes referred to as "poultice action". If the material forming the poultice is not inert but contains acid or alkaline material that may be leached out, the rate of attack is increased markedly; and if salts of heavy metals are also present, the attack is accelerated still further by electrolytic action. When it is known that the aluminum surface is likely to be subjected to poultice action, adequate protection should be provided by painting.

Another common condition that prevents free access of air to the surface occurs in crevices between contacting surfaces in joints. Moisture is carried into the joint by capillary action, and corrosion is accelerated by oxygen concentration cells set up because of lack of free circulation of air. Unless the joint is dried frequently, the corrosion product holds moisture and retards the formation of a protective film. The corrosion products of aluminum occupy several times the volume of the metal and, hence, exert sufficient pressure to spread the joint. This permits more moisture to enter the joint, and the corrosion process continues. Under such conditions, it is recommended that the contact surfaces be painted before assembly, even though in many instances the surfaces subjected to free circulation of air require no protection from paint. Where a joint is made between aluminum and a dissimilar metal such as iron or steel, the corrosion is greatly aggravated by electrolytic action between the metals. In such situations, it has been found desirable to spray the steel surface with aluminum or zinc and to impregnate the sprayed coating with a good paint. When the steel is covered thus, chances of electrolytic action are greatly minimized. The use of a permanently plastic joint compound to seal the joints from moisture, is recommended regardless of other protective measures. With a satisfactory compound, painting the contact surfaces may sometimes be omitted.

Many of the wrought alloys are commonly used without protection. These include alloys which do not respond to heat treatment (2S, 3S, 4S, 52S, Alclad 3S and Alclad 56S) and the heat treatable alloys of the magnesium silicide type (53S, 61S and 63S), as well as the Alclad high-strength alloys (Alclad 24S-T4, R301, Alclad 14S-T6 and Alclad 75S-T6). The wrought aluminum-copper alloys not in Alclad form, 75S-T6 and R303, as well as A51S, are ordinarily painted when exposed to the atmosphere.

Of the casting alloys, the aluminum-silicon alloy 43 has been used extensively in the construction of buildings without the protection of paint. The backs of spandrels made of 43 alloy have sometimes been painted. Although they are less frequently used, it now seems evident that the cast aluminum-copper or aluminum-copper-silicon alloys will also resist weathering satisfactorily without protection. The aluminum-magnesium alloys, 214 and 218, have a higher resistance to corrosion and a tendency to maintain a whiter appearance under conditions of atmospheric exposure; hence, these alloys are often used for highly ornamental work.

Resistance to Waters. Aluminum equipment is established as standard for storing and conveying distilled water of the highest purity.[15] During the initial period of contact, the reaction that takes place with the distilled water is

sufficient to form a protective film of hydrated aluminum oxide on the metal surface; but this action soon stops and, even with boiling water, the purity of distilled water is not affected to a practical extent by contact with these aluminum alloys. Commercially pure aluminum, 2 S, and such alloys as 3 S, 52 S, 43, 214, B214 and 406 have been used successfully. Equipment constructed of these alloys is coming into use also for storing and conveying demineralized waters, used in processes where contamination by even small traces of certain elements cannot be tolerated.

A considerable amount of aluminum equipment made of 2 S, 3 S, 52 S, 43, 214, B214 and 406, has been used to convey and store a number of lake, river and municipal waters —in some instances, at elevated temperatures. However, the variation in composition of waters from different sources is so great that it is not possible at present to predict their action on aluminum and, hence, to generalize regarding the mutual compatibility of aluminum alloys and miscellaneous waters. Alkaline waters have usually been found to have appreciable action on aluminum alloys, although there are exceptions to this generalization. In some instances this action has been prevented by the addition of suitable chemical inhibitors. Waters of high acidity, such as are often encountered in coal mines, are generally corrosive to aluminum, but in a number of situations, aluminum alloys have proved to be more resistant than other metals used in such service. When small amounts of cathodic metals such as copper and nickel are present in natural waters or have been picked up by contact with other metallic equipment, these waters have been found to be corrosive to aluminum. The heavy metal ions are reduced by aluminum and the deposition of the heavy metals on the aluminum surface causes the aluminum to pit. Because Alclad 3 S has been found to combat the pitting action successfully, this product is being used widely for the handling of such corrosive waters. Moisture in the form of water vapor causes very little action on aluminum alloys at temperatures as high as 300 F.

Aluminum alloys such as 2 S, 3 S, 4 S, 52 S, 53 S, 214, B214 and the alclad products, have been found to resist the action of sea water. The alloys 52 S, 214 and alclad products are outstanding in this respect.[5]

Aluminum Alloys for Chemical Equipment. Aluminum alloys have been used widely for processing, handling and storing different types of chemical solutions. The chemical industry has so many ramifications that only a general survey with a few specific examples can be given here. It should be emphasized that even small quantities of impurities in the chemical solutions, and other seemingly unimportant factors, may make the difference between success and failure of aluminum alloys in a given application.

Potentials in Various Solutions. The potentials given in Table I cannot be used to predict the resistance of aluminum to corrosion while in contact with dissimilar metals in many types of chemical solutions. Table V indicates that the potential of aluminum varies to a marked degree with the composition of the solution. In the use of aluminum in the chemical industry, the effect of the composition of the solutions on the potentials of aluminum must be considered carefully for each application if the galvanic effects resulting from dissimilar metals are to be avoided.

Acid Solutions. Organic. Nearly all organic acids can be used in contact with such aluminum alloys as 2 S, 3 S, 52 S, 53 S and 61 S; for example, at room temperature the rate of attack on aluminum by any concentrations of aqueous solutions of acetic acid, is not more than 0.0044 in. per year. The rate of attack increases markedly with increasing temperature; however, commercial glacial acetic acid does not attack aluminum appreciably even at temperatures as high as 120 F. Formic and oxalic acid solutions attack aluminum alloys at appreciable rates, so aluminum alloys are not generally used for handling these materials except in processes where it is necessary for the resulting products not to be discolored or for the solution to retain its water whiteness.

Acid Solutions. Inorganic. Dilute aqueous solutions of the mineral acids, such as HCl, H_2SO_4, H_3PO_4, and HNO_3, react with aluminum at appreciable rates. Aluminum alloys are used with these solutions to a limited extent, generally where it is desirable to maintain the water whiteness of the solution or to prevent the discoloration of the products that are being processed. Organic coatings have been applied to certain types of aluminum equipment for the handling of dilute mineral acids. Nitric acid, in concentrations greater than 80% by weight, has a negligible action on aluminum; consequently, aluminum alloys are used to make tanks and drums for fuming nitric acid. Salts that hydrolyze to give acid solutions can be handled in aluminum equipment. For example, aluminum alloys are used widely in contact with ammonium nitrate solutions and, in many instances, have been employed safely in contact with ammonium sulfate and ammonium aluminum sulfate solutions.

Alkaline Solutions. Aluminum is attacked by many aqueous alkaline solutions because of their solvent effect on the protective oxide film. There are notable exceptions, as indicated by the extensive use of aluminum equipment to handle and manufacture ammonia, not only in the liquid and vapor states, but also in aqueous solutions. After a minor initial action with these chemicals, a protective film is re-formed on the aluminum surface. For a similar reason aluminum alloys are usually satisfactory in contact with a number of organic amines. The addition of sodium silicate or sodium chromate can greatly minimize or even prevent the attack on aluminum by solutions of salts that hydrolyze to give basic solutions such as sodium carbonate and trisodium phosphate.

Table V. Effect of Composition of Electrolyte on the Potential of Aluminum[a, b]

Electrolyte	Potential, volts 0.1 N Calomel Scale
Reversible potential calculated from heat data for aluminum ion concentration of one molal activity	— 2.11
M[c] $AlCl_3$	— 1.11
M NaCl	— 0.85
M Na_2SO_4	— 0.50
M HCl	— 0.71
M HNO_3	— 0.88
M NaOH	— 1.47

Sat Sol[d] $Ca(OH)_2$	— 1.54
Sat Sol $Ba(OH)_2$	— 1.53
M Na_2CO_3	— 1.35
M Na_3PO_4	— 1.32
Sat Sol $CaCO_3$	— 1.04
Sat Sol $CaSO_4$	— 0.77

(a) Data from Aluminum Research Laboratories
(b) Alloy 2 S–O
(c) M indicates one gram molecular weight of the compound per liter of solution
(d) Sat Sol indicates saturated solution of compound

Neutral Salt Solutions. Neutral inorganic salt solutions cause very little action on aluminum, but the simultaneous presence of some of the cathodic metals and chlorides may cause appreciable acceleration of attack. The action of neutral solutions of chloride salts is slow unless they are contaminated with heavy metals such as copper, nickel and lead. Aluminum alloys are used for piping chloride brines from oil wells. At room temperature the accelerating effect of the presence of the heavy metal impurities can be inhibited by the addition of chromates. Aqueous solutions of neutral sulfates and neutral nitrates are not corrosive to aluminum.

Sulfur and Sulfur Compounds. Aluminum alloys are particularly resistant to the action of elementary sulfur, even when it is molten or in the form of vapor, and to the action of a number of sulfur compounds that corrode many other metals. Tests have shown that aluminum alloys resist "sour" crude oils containing large amounts of hydrogen sulfide. Processes to eliminate H_2S from the "sour" crudes use equipment made of aluminum alloys.

Stability of Chemicals. In the handling or processing of a number of chemicals, aluminum alloys are used not only because they resist chemical attack but also because they do not act to decompose the compounds catalytically. The decomposition of hydrogen peroxide is not accelerated by aluminum nor is the aluminum attacked; consequently,

Table VI. Aluminum Alloys for the Construction of Equipment for Processing or Handling Industrial Chemicals[a]

Process or Chemical	Equipment	Alloy
Acetic acid	Distillation columns, *condensers, receivers, storage tank cars, drums, piping, oxidizing kettles,* and the like	2S, 3S, 52S, 61S-T6, Alclad 3S, 43, 214, B214, 356,406
Acetic anhydride	Heat exchangers, reaction vessels, *piping, storage tanks,* drums, *tank cars*	As above
Ammonium nitrate	*Ammonia tanks,* reaction vessels, tanks, *evaporators, crystallizers,* piping, drums, *tank cars*	As above
Ammonium hydroxide	Absorbers, *condensers, dephlegmators, piping*	As above
Edible oils and fats	*Deodorizers,* bleachers; winterizing equipment, including stills, separators, *condensers,* traps, bleachers, filters, pumps, *tanks, piping;* drums, tank cars	As above
Fatty acids	*Condensers, storage tanks,* trays, filter presses, receivers, drums, *melting vessels*	As above
Formaldehyde	Scrubbers, *receivers, storage tanks,* condensers, drums, *tank cars*	As above
Glue and edible gelatin	Vats, *evaporators, tanks,* heat exchangers, cooling towers, pumps, chutes, screens, spreaders, molds, filters, *piping*	As above
Hydrogen peroxide	*Stills,* condensers, receivers, *storage tanks, piping,* pumps, *drums, tank cars*	99.6% Al, 2S, 52S, 43, 214, B214, 356
Naval stores	*Stills, condensers,* receivers, *storage tanks,* evaporators, *piping, drums, tank cars*	2S, 3S, 52S, 61S-T6, Alclad 3S, 43, 214, 356, 406
Refrigerants	*Compressors, heat exchangers, evaporators, receivers, tubing*	2S, 3S, 17S-T4, 24S-T4, 52S, 61S-T6, Alclad 3S, 43, 214, B214, 356, 406
Ammonia, Carbon dioxide, Freons (11, 12, 21, 22, 113, 114), Methyl formate, Sulfur dioxide		
Soda ash manufacture	Equipment for handling ammonia, carbon dioxide, and brines, including *heat exchangers,* stills, *piping,* receivers, *absorbers,* reaction columns	2S, 3S, 52S, 61S-T6, Alclad 3S, 43, 214, B214, 356, 406
Water Distilled De-ionized	*Storage tanks, piping, condensers, receivers, degasifiers*	As above

(a) The *italicized* items have been constructed of aluminum alloys. Laboratory tests indicate that aluminum alloys deserve consideration for the fabrication and service testing of the items not italicized.

pure aluminum containers are used for storage and shipment of this material.[16] It has been found that aluminum alloys such as 2S, 3S, 52S, 53S and 61S-T6 are not attacked by mineral and vegetable oils, nor do they catalyze the decomposition of these products.[17,18] Pure aluminum equipment is used to produce citric and gluconic acids from sugars by the fermentation process, not only because pure aluminum resists attack by these solutions, but also because it is one of the few metals that has no harmful effect on the organisms.

Refrigerants. Even if some water is accidentally introduced into the refrigerating system, a wide variety of refrigerants can be handled in equipment made of aluminum alloys such as 2S, 3S, 52S, 53S and 61S. These alloys are affected to a negligible extent and do not affect the refrigerant adversely. In tests that were conducted at a temperature of 45 C, employing either dichloro-difluoromethane (F12) with 5% added water, or ammonia with the same amount of water, in contact with 3S, the maximum rate of penetration was found to be less than 0.002 in. per year.[19] When 3S was in contact with either of the above materials, dry or with dry sulfur dioxide, the attack was much less.

Chemical Equipment. In Table VI the italicized items of aluminum equipment have given satisfactory service with the chemicals or in the processes listed. Laboratory tests indicate that the aluminum alloys listed deserve consideration and service testing for the items not italicized. Materials that are now being shipped in aluminum-tank cars are given in Table VII.

Table VII. Chemicals Now Transported in Aluminum-Tank Cars

Chemical	Alloys Used for Tanks
Acetic acid	3S, 4S
Acetic anhydride	3S, 4S
Ethyl acetate	Alclad 17S-T4
Fatty acid	3S, 61S
Formaldehyde	3S
Glycerin	61S
Hydrogen peroxide	2S
Naphthenic acid	3S
Nitric acid	61S
Water-white rosin	3S

Aluminum for the Preparation and Processing of Foods. Because of the mutual compatibility between foods and aluminum equipment, aluminum alloys are widely used in the preparation and processing of foods. Aluminum cooking utensils, generally made of 2S, 3S or 52S sheet, or 43 or B214 casting alloys, give excellent service. Alclad 3S has been found very satisfactory for teakettles, in spite of the severe service to which they are subjected. Directly fired or jacketed kettles, ordinarily made of 3S or 52S, are used extensively for the heating of foods and fruit juices in bulk. Aluminum equipment has been used satisfactorily for years for storing, processing, or handling a number of food products such as fruit juices, milk, fish, meats, various vegetables, wines and beer. The wrought alloys usually employed are 2S, 3S, 52S, 53S and 61S, and the cast alloys are 43, 214, B214, 356 and 406.

The Metallography of Aluminum Alloys

By F. Keller*

THE methods in general use for the metallographic examination of aluminum alloys are similar to those employed for other metals, except that more care must be taken to avoid the formation of flowed metal and deep scratches during polishing. The polishing and etching procedures described here have been in use for many years and have been found generally satisfactory for all products and tempers of aluminum alloys.

Preparation for Macroscopic Examination. Macroscopic examination of aluminum products for soundness, cracks, inclusions, folds and seams, as well as for grain structure and grain flow, is aided by the use of etching practices that clean the surface, make defects more prominent and reveal the general macrostructure. The practices that should be employed depend on the character of the product and on the types of information desired.

In instances where only the surface structures of ingots, billets, forgings and other articles are of interest, no surface preparation other than degreasing is necessary before etching. In problems involving the use of the more active etching solutions, a fairly smooth saw cut will often provide a satisfactory surface. A reasonably good finish is necessary; otherwise the finer details of the macrostructure may be obscured. For some types of examination a fairly satisfactory finish can be obtained by surfacing the sample on an abrasive belt, provided excessive metal flow is avoided. The best preparation for macro-etching, however, consists in obtaining a smooth, uniform surface by machining the sample on a lathe or a shaper.

All oil, grease, dirt and other foreign materials should be removed by some suitable cleaning method before etching is attempted. Special cleaning is not required when a sodium hydroxide solution is used for etching, since this solution is an effective cleaner. When other etching solutions are used, the cleaning may be accomplished by a preliminary treatment in a 5% sodium hydroxide solution or by the use of other cleaning agents, such as carbon tetrachloride, ethylene dichloride or one of the proprietary cleaners.

Etching to Reveal Macrostructure. Etching is usually done by immersing the sample in the etching reagent, by swabbing with the reagent, or by pouring the reagent onto the surface. It is very important to apply the etching reagent to the surface as uniformly as possible. Different times of etching will be required for different alloys and different tempers of the same alloy. Under any circumstances, etching should be continued until the desired contrast is obtained, but prolonged etching should be avoided, since it may cause excessive roughening of the surface, thus obscuring some of the macrostructural features. In some instances, the use of the less active solutions is desirable to avoid excessive roughening. This is especially important when the specimens are to be examined at magnifications of 10 to 25 diam.

Etching Solutions for Revealing Macrostructure. The solutions in general use for revealing soundness, grain size, grain flow and grain structure on a macroscopic scale for various aluminum alloy products, are listed in Table I.

Preparation for Microscopic Examination. For microscopic examination, it is usually necessary to cut specimens of a convenient size for polishing. These can be obtained by sawing or shearing, but care should be taken to avoid overheating the specimen or altering the structure in any manner. The next step in the preparation of a metallographic specimen is the removal of all oil, grease, dirt and other foreign material. Specimens too small to be handled conveniently during polishing should be mounted in some manner. The mounting of specimens can be accomplished in several ways. For instance, with samples of sheet, a pack can be made by binding a number of pieces of sheet together by means of machine screws. In the making of a composite specimen of sheet or foil, the pieces assembled in the pack are sometimes separated by filler pieces of an aluminum alloy. Other

Table I. Etching Solutions for Revealing Macrostructure

Solution	Concentration	Specific Use	Procedure
Sodium hydroxide	NaOH ..... 10 g Water ..... 90 ml	General-purpose macro-etch for cleaning surfaces, revealing unsoundness, cracks and gross defects	Dip sample 5 to 15 min in solution heated between 140 and 160 F; wash in water, remove deposit of etching products with conc HNO_3 and rinse with water. Can be used on original surface or after a reasonably good saw or machine cut.
Aqua regia—HF	HCl (conc) ..... 75 ml HNO_3 (conc) ..... 25 ml HF (48%) ..... 5 ml	For revealing grain structure of castings and of alloys of the 3 S, 52 S, 53 S and 61 S type	Apply by immersion or swabbing until desired contrast is obtained. Wash specimen with warm water to speed up drying. Special surface preparation not required.
Tucker's etch	HCl (conc) ..... 45 ml HNO_3 (conc) ..... 15 ml HF (48%) ..... 15 ml Water ..... 25 ml	General-purpose macro-etch for revealing structure of castings, forgings and such	Etch by immersion of part or sample until desired grain contrast is obtained; rinse with warm water and dry. Can be used after a reasonably good saw cut or machine cut.
Modified Tucker's etch	HCl (conc) ..... 10 ml HNO_3 ..... 10 ml HF (48%) ..... 5 ml Water ..... 75 ml	General-purpose macro-etch for revealing structure of all castings and forgings except high-silicon alloys	Etch by immersion or swabbing until desired grain contrast is obtained; rinse with hot water and dry. Can be used after a good machine cut.
Hydrofluoric acid	HF (48%) ..... 10 ml Water ..... 90 ml	General-purpose macro-etch for revealing structure of high-silicon alloy castings and forgings	Etch by immersion until desired grain contrast is obtained; rinse in hot water and dry. Use after a polish with alundum flour on broadcloth.
Flick's etch	HCl (conc) ..... 15 ml HF (48%) ..... 10 ml Water ..... 90 ml	General-purpose macro-etch for revealing grain structure of duralumin-type alloys	Apply by immersion or swabbing until good grain contrast is developed. Rinse with water and remove deposit of etching products with conc HNO_3; wash with warm water. For best results, a smooth machined surface or a surface obtained by rubbing on 180 Aloxite cloth is required.
Keller's etch	HF (48%) ..... 0.5 ml HCl (conc) ..... 1.5 ml HNO_3 (conc) ..... 2.5 ml Water ..... 95.0 ml	For revealing finer details of macrostructure of duralumin-type alloys and for showing grain contrast	Etch by immersion for 15 sec to 1 min; wash with warm water and dry. Do not remove etching products from surface. Samples should be carried through regular metallographic procedure to the final operation.

metals should not be used as filler pieces in composite specimens. The pack should be clamped tightly to minimize capillary retention and subsequent exudation of solutions from crevices.

The general practice is to embed any small or irregular-shaped specimen in a mounting medium. The most economical and convenient method consists in placing the specimen in a ring of aluminum tubing and filling the ring with melted sulfur. Sulfur does not chip during polishing and is unaffected by the etching reagents commonly used. Other mounting materials, such as sealing wax or dental cement, may be employed. If a press for mounting specimens is available, Bakelite or one of the transparent or semitransparent plastics can be used. It is important to avoid any mounting material that will cause galvanic attack during etching or that is severely attacked during the etching procedure.

The following procedure is recommended for the preparation of specimens for microscopic examination:

1 Draw the specimen over a long-angle lathe file to obtain a plane surface and to remove any distorted metal from sawing operations.

2 Rub specimen on 180-grain Aloxite paper to remove file marks, and then successively on No. 0 and 000 metallographic emery papers that have been coated with a solution of paraffin and kerosene. This coating helps keep the specimen bright and prevents particles of abrasive from becoming embedded in the surface. The solution is made by dissolving 50 g of paraffin in one liter of kerosene. The specimen should be turned about 90 deg to the direction of polishing, at each step in the process.

3 Polish on a rotating disk covered with "kitten's ear" broadcloth or "Gamal" cloth, using a water suspension of 600 alundum flour or a similar material as the abrasive. A quantity of the abrasive is placed in a flask with water and is shaken until it is in suspension. In this way, the mixture can be conveniently supplied to the pad while the specimen is being polished. The polishing disk should be operated at about 250 to 300 rpm and the specimen should be held on the pad about 2 to 3 in. from the center of the disk. The pad should finally be washed free of the coarser particles of the abrasive by means of a stream of water from a wash bottle, and the polishing with this abrasive should be completed by using a suspension from which all the coarse particles have settled.

4 Polish finally on a rotating disk covered with "kitten's ear" broadcloth or "Gamal" cloth and operated at a speed of 150 to 200 rpm, using heavy magnesium oxide powder as the polishing medium. The pad should be kept moist with *distilled water* and a small quantity of the magnesium oxide should be worked into it with the palm of the hand. Any gritty particles or excess powder should be brushed off. During polishing, the pad should be kept moist by adding *distilled water* from a wash bottle as needed. Polishing should be continued until the striations from the alundum operation (3) are removed. As the polishing operation approaches completion, the pad should be washed nearly free of magnesium oxide and the specimen should be held on the slowly rotating pad while a copious supply of distilled water is used. The pressure and time required for polishing a specimen are influenced by both the composition and the temper of the specimen.

5 When a satisfactory polish has been secured, the specimen should be washed in a stream of warm tap water and dried by blowing the excess water from the surface. The polished surface should not be touched or rubbed against anything; otherwise the finish may be marred. Specimens will retain their finish indefinitely, provided they are kept in a place where dust and dirt from the

atmosphere will not collect on the surfaces. The proper appearance of the surface of an aluminum alloy at various stages in the preparation is illustrated by Fig. 1.

Several precautions must be taken to secure satisfactory results during the polishing of aluminum alloys. For example, there are several grades of magnesium oxide powder prepared specifically for metallographic use and employed successfully for polishing some metals; however, several of these products are somewhat alkaline and will etch an aluminum specimen. Magnesium oxide powder of this type should not be used. The use of *distilled water* with the magnesium oxide is very important. When ordinary tap water is used, hard carbonate particles may form and cause deep scratches that cannot be removed without going back to the operations on the abrasive papers. Finally, a new polishing cloth should be boiled for several hours to soften the fibers before it is used. When the cloth is not in use, it should be kept moist in distilled water that has been acidified slightly with hydrochloric acid.

Etching Solutions for Microscopic Examination. Metallographic specimens are etched to remove flowed metal from the polished surface and to aid in revealing the microstructure by coloring or attacking the various constituents or phases. The type of etching solution required varies with the magnification to be used in subsequent examination, as well as with the purpose for which the etching solution is being employed.

Etching is accomplished by either of two methods, immersion or swabbing. The practice of swabbing specimens with a dilute solution of hydrofluoric acid or sodium hydroxide has been found to give uniform or satisfactory results in removing surface flow and in outlining constituent particles. Experience has shown that the temperature of both specimen and etching reagent, the concentration of solution and the time of etching should be controlled to give useful results. Information concerning the etching solutions that are employed for the identification of constituents and for revealing the general microstructural features of various aluminum alloys is given in Table II. These are all aqueous solutions made by volume when acids are used, and otherwise by weight.

Constituents in Aluminum Alloys. In the metallographic examination of aluminum alloys, it is frequently necessary to identify the constituents that appear in the microstructure. In general, the constituents in aluminum alloys consist of (1) elements such as silicon that do not combine with aluminum to form compounds and therefore are present in the elemental state; (2) intermetallic compounds formed by ▪ combination of one or more alloying elements with aluminum ($CuAl_2$ and $FeAl_3$); (3) intermetallic compounds that are formed by a combination of two or more elements other than aluminum and that are stable in aluminum (for example, Mg_2Si); and (4) ternary or more complex constituents, as for instance, α(Al-Fe-Si) and Al-Cu-Fe-Mn.

Identification of Constituents. The first attempt to identify constituents should be made on the unetched specimen, using color and manner of occurrence as a means of differentiation. Some of the more common constituents, such as $CuAl_2$, Si, Mg_2Si and β Al-Mg, can be identified readily by their polishing characteristics, color and manner of occurrence. Others, more difficult to identify, are sometimes present and necessitate the use of various etching reagents.

For judging the color of constituents, it is advisable to employ light approximately the color of daylight. Addition of a Wratten 78A filter, which has a bluish tint, converts the light of a carbon-arc lamp with an Eastman neutral tint filter to approximately that of daylight. Any white light will give about the same results, although the use of the 78A filter will help in the separation of different constituents. Examination for identification is usually made at a magnification of 500 diam with a lens combination comprising a 4-mm objective and a 10× ocular.

Etching Chart. In Table III are given the etching characteristics of the principal constituents found in "as-polished" specimens of commercial aluminum alloys after the etching reagents described in Table II have been used.

Fig 2 Sand-cast 43 alloy (5% Si). × 500

Microstructure of Aluminum Alloys. Commercial aluminum alloys are generally of the hypoeutectic type and solidification begins with the separation of aluminum or aluminum-rich solid solutions as primary dendrites. During solidification of these dendrites, the alloying constituents tend to concentrate in the remaining liquid phase, producing a structural condition known as "coring" and a discontinuous or continuous network of constituents at interstices of the dendrites and along the grain bound-

Table II. Etching Solutions for Revealing Microstructure

Solution	Concentration	Specific Use	Procedure
Hydrofluoric acid	HF (48%) ..... 0.5 ml H_2O ..... 99.5 ml	General-purpose micro-etch	Swab with soft cotton swab for 15 sec.
Sodium hydroxide	NaOH ..... 1 g H_2O ..... 99 ml	General-purpose micro-etch	Swab specimen with solution for 10 sec.
Sodium hydroxide	NaOH ..... 10 g H_2O ..... 90 ml	General-purpose micro-etch	Immerse specimen for ▪ sec at 70 C and rinse in cold water.
Sulfuric acid	H_2SO_4 (conc) ..... 20 ml H_2O ..... 80 ml	For separating Al-Cu-Fe-Mn from Al-Fe-Mn or α(Al-Cu-Fe)	Immerse for 30 sec at 70 C and quench in cold water.
Nitric acid	HNO_3 (conc) ..... 25 ml H_2O ..... 75 ml	For separating α(Al-Fe-Si) from $FeAl_3$	Immerse for 40 sec at 70 C and quench in cold water.
Keller's etch	HF (conc) ..... 1.0 ml HCl (conc) ..... 1.5 ml HNO_3 (conc) ..... 2.5 ml H_2O ..... 95.0 ml	For revealing microstructure of heat treated duralumin-type alloys	Etch by immersion for 10 to 60 sec, wash with warm water and blow dry. Do not remove etching products from surface.
Modified Keller's etch	HF (conc) ..... 1.0 ml HCl (conc) ..... 1.5 ml HNO_3 (conc) ..... 10.0 ml H_2O ..... 87.5 ml	For separating 75S-W from 75S-T6 alloy	Etch by immersion for 10 to 60 sec, wash with warm water and blow dry. Do not remove etching products from surface.

Table III. Etching Characteristics of Constituents in Aluminum Alloys

Constituents	Reagent					
	0.5% HF, swab for 15 sec, wash in cold water	1% NaOH, swab for 10 sec, wash in running water	20% H_2SO_4 at 70 C, immerse specimen for 30 sec, quench in cold water	25% HNO_3 at 70 C, immerse specimen for 40 sec, quench in cold water	10% NaOH at 70 C, immerse specimen for 5 sec, rinse in cold water	0.5% HF, 1.5% HCl, 2.5% HNO_3, immerse specimen for 15 sec, rinse in warm water
Silicon	Outlined Unattacked Color lightened	Outlined. Unattacked Color slightly lightened	Unattacked Color lightened	Outlined Unattacked Color lightened	Outlined Unattacked Color lightened	Outlined Unattacked Color lightened
Mg_2Si	Colored bright blue	Outlined Color unchanged	Action violent Some particles dissolved, any left have a blue color	Colored brown or black	Outlined Color lightened	Outlined Colored blue to brown
$CuAl_2$	Outlined. Part of pinkish tinge removed. Constituent light and clear	Outlined. Part of pinkish tinge removed Constituent light and clear	Outlined. Part of pinkish tinge removed. Constituent light and clear	Colored brown or black	Pitted Colored light to dark brown	Outlined Constituent light and clear
β (Al-Mg)	Outlined. Slightly clearer and more watery Black pits appear in particles	Not outlined Unattacked Uncolored	Attacked vigorously resulting in pitting. Some particles dissolved	Heavy attack Particles grayish and watery	Outlined Unattacked Uncolored	Heavily outlined Attacked by pitting
$FeAl_3$	Slightly darkened Brown stains appear on large primary particles	Outlined Slightly darkened	Heavily attacked Particles often dissolved or deeply pitted Color darkened	Outlined, Contrast with Al-Fe-Si improved	Outlined Colored deep brown	Outlined Uncolored Slightly attacked
α (Al-Fe-Si)	Outlined Uncolored	Outlined Uncolored	Outlined Blackened and attacked	Outlined, Contrast with $FeAl_3$ improved	Attacked Blackened	Heavily outlined Darkened and roughened
β (Al-Fe-Si)	Blackened and attacked	Outlined Uncolored Unattacked	Outlined Slightly darkened and pitted	Outlined Uncolored Unattacked	Outlined Slightly darkened and attacked	Outlined Slightly darkened and roughened
Al-Mn	Outlined Slightly darkened	Attacked. Colored brownish or bluish but coloring is uneven	Outlined Uncolored Unattacked	Not outlined Unattacked Uncolored	Colored blue or brown	Outlined Unattacked Uncolored
$NiAl_3$	Outlined Colored blue and brown	Outlined Darkened slightly Uncolored	Outlined Darkened slightly Uncolored	Outlined Uncolored Unattacked	Colored blue to deep brown	Colored brown to black
Al-Fe-Mn	Outlined Colored brown (Sometimes bluish)	Outlined Particles pitted (Often a rough blue color on a few particles)	Outlined Unattacked Uncolored	Outlined Unattacked Uncolored	Colored deep brown to blue	Outlined Attacked Darkened
Al-Cu-Ni	Outlined Unattacked Darkened	Outlined Slightly darkened Unattacked	Outlined Slightly darkened Unattacked	Blackened Some particles dissolved	Outlined Unattacked Uncolored	Outlined Some large particles stained unevenly
α (Al-Cu-Fe)	Outlined Blackened	Outlined Unattacked Uncolored	Outlined Unattacked Uncolored	Outlined Unattacked Uncolored	Outlined Blackened Attacked	Blackened
β (Al-Cu-Fe)	Outlined Unattacked Uncolored	Outlined Slightly darkened	Outlined and uncolored. Often show black cores which are probably $FeAl_3$	Outlined Slightly darkened Unattacked	Pitted Colored light brown	Outlined Blackened
Al-Cu-Fe-Mn	Outlined. Colored light brown to black Usually appears roughened	Outlined Uncolored	Outlined Blackened	Outlined Unattacked Uncolored	Outlined Uncolored	Outlined Colored brown to black
Al-Mn-Si	Outlined. Colored light brown to black Usually appears roughened	Outlined Usually appears rough and attacked Slightly darkened	Outlined. Appears rough and attacked Darkened slightly	Outlined Appears rough Darkened slightly	Outlined Attacked Color not changed	Outlined Slightly darkened
Al-Cu-Mg	Outlined Blackened	Outlined Colored light brown	Outlined Attacked Blackened	Outlined Attacked Blackened	Outlined Unattacked Colored brown	Colored brown to black
$CaSi_2$	Colored blue Heavily outlined	Outlined Color unchanged	Outlined Colored blue Roughened	Outlined Unattacked Uncolored	Outlined. Blackened Attacked and roughened	Colored brown to blue Mottled
Al-Cu-Mn	Outlined Attacked Blackened	Outlined Unattacked Uncolored	Outlined Colored light brown	Outlined Unattacked Uncolored	Outlined Attacked Blackened	Attacked Blackened
$CrAl_7$	Outlined Unattacked Uncolored	Outlined Unattacked Uncolored	Outlined Unattacked Uncolored	Outlined Unattacked Uncolored	Outlined Colored blue to brown unevenly	Outlined Unattacked Uncolored

aries. Further changes in structure result from different rates of cooling after solidification, and from various thermal and mechanical treatments. The constituents in aluminum alloys are found at the interstices of the dendrites and along grain boundaries in the as-cast condition, and are generally distributed throughout the matrix in material in the wrought condition. The microstructure of castings is governed largely by chemical composition, rate of solidification and thermal treatment. The microstructure of wrought products is influenced also by type and amount of working, as well as by the various thermal treatments that the products receive.

The structure of aluminum castings and of ingots is heterogeneous therefore, and is characterized by a dendritic pattern with a continuous or discontinuous network of microconstituents. Typical microstructures of two aluminum casting alloys in the as-cast condition are illustrated by Fig. 2 and 3. When an alloy of the type shown in Fig. 3 is subjected to a solution heat treatment, appreciable changes occur in the microstructure. The soluble constituent in the network will dissolve and the matrix will become a solid solution with no evidence of coring. The type of structure produced by heat treatment is shown in Fig. 4. The mechanical properties of an alloy of this type can be further improved after the solution treatment by employing a precipitation treatment, which will decrease

the grain contrast and may cause a noticeable precipitate along grain boundaries and within grains. The structure of the same alloy as in Fig. 3 is shown in Fig. 5 as it appeared after receiving a solution treatment and a precipitation treatment.

When cast aluminum ingots are made into various wrought products by rolling, forging, extruding or drawing, the macrostructure and microstructure are altered according to the type and degree of working, as well as by subsequent thermal treatments. Hot working breaks up the relatively large as-cast grains into fibers or fragments that may or may not recrystallize as new grains during working. The original cast grains are flattened and elongated according to the type and extent of working. Figure 6 illustrates the microstructure of a hot worked alloy of the 17 S type.

After the structure of aluminum alloy products has been refined by hot working, further working can be done below the recrystallization or annealing temperatures, causing additional refinement of the structure by breaking the grains into fragments and changing the constituent pattern. In cold worked material, work lines are frequently apparent in the microstructure, making it difficult to reveal any evidence of grain boundaries by etching. The microstructure of a cold worked aluminum alloy (2 S-H18) is shown in Fig. 7.

Annealing of cold worked aluminum alloys causes recrystallization and the formation of new grains from the grain fragments produced by cold working. With some alloys and with small amounts of cold working, it is not always possible to determine by metallographic examination whether or not recrystallization has occurred. Usually, however, annealed alloys are characterized by a more or less equiaxed grain structure that can be revealed readily by etching. A typical example of the structure of annealed aluminum sheet (2 S-O) is shown by Fig. 8. Besides causing recrystallization, the annealing treatment for heat treatable aluminum alloys must cause sufficient precipitation and agglomeration of the hardening constituents to produce the maximum degree of softening. The microstructure of 24 S-O alloy sheet, shown in Fig. 9, is characteristic of the type of structure obtained in a strong aluminum alloy in the annealed condition.

When an aluminum alloy of the heat treatable type is subjected to a solution heat treatment, marked changes occur in the microstructure. The most important change results from solution of the various hardening constituents during the heating cycle and subsequent retention of these components in solid solution as a result of the quenching operation. Thus, the microstructure of an aluminum alloy that has received a solution heat treatment is essentially that of a solid solution of the various elements in aluminum. This type of microstructure is illustrated by the micrograph of 14 S-T4 alloy shown in Fig. 10. It is typical of all aluminum alloys that have copper as their principal hardening component. After heat treatment, a few particles of the constituents will usually be apparent in the microstructure. These are residual particles of the soluble hardening constituents that have not been dissolved by the solution heat treatment, and particles of some of the relatively insoluble constituents that are present in the particular alloy.

Immediately after quenching from a solution heat treatment, the material will have a degree of workability and strength intermediate between that of the fully annealed condition and that of the heat treated temper. In the course of several days subsequent to quenching, some of the dissolved hardening elements will precipitate from solid solution as submicroscopic particles of the optimum size, number and dispersion to harden and strengthen the material appreciably. Most of the heat treatable aluminum alloys have, to a variable degree, this tendency to age harden at room temperature after a solution heat treatment.

The particles of precipitate that are responsible for the precipitation hardening of these alloys at room temperature are much too small to be resolved by the optical microscope; thus, they will not be apparent in the microstructure. Some aluminum alloys, however, do not age harden to their maximum strength at room temperature and must be given a precipitation treatment to cause the age hardening action to reach completion. This applies to alloys of the 14 S, 18 S, 25 S, 51 S, 53 S, 61 S and 75 S types. In these alloys, the tensile and yield strengths are further increased by the precipitation heat treatment following a solution heat treatment, but the ductility and workability are decreased. The effects of a precipitation heat treatment are usually evident in the microstructure, especially in alloys containing copper. After a precipitation heat treatment, alloys of the copper-containing type will show considerably less grain contrast on etching and will have very fine particles along the grain boundaries and within the grains. The structure of a precipitation hardened alloy of the 14 S type is illustrated by Fig. 11.

Properties of Aluminum-Copper Alloys

By E. H. Dix, Jr.* and J. J. Bowman*

OF the alloying elements used in aluminum alloys, copper was one of the earliest employed commercially and for many years has been the principal one, especially in this country. Even today copper is an important constituent of many of the most commonly used commercial alloys. When copper is the principal alloying element, two copper contents are of the greatest importance; namely, about 8% for castings and about 4% for both castings and wrought products. Alloys containing 4% Cu are nearly always used in the heat treated condition.

Casting Alloys. The commercial aluminum-copper casting alloys ordinarily contain controlled amounts of iron and silicon and sometimes small amounts of other elements, such as titanium or boron for special purposes. The casting and general foundry characteristics of these commercial aluminum-copper alloys are very good. The addition of copper decreases shrinkage difficulties and hot shortness progressively. Although the 8% Cu alloy is a good general-purpose alloy, its commercial importance is decreasing and the alloys containing about 4% Cu and substantial amounts of silicon are replacing it to a great extent. The commercial 4% Cu casting alloy is usually employed in the heat treated condition. Although considerably higher mechanical properties are possible with alloys of high purity, the high-purity alloys have achieved no importance commercially because the casting characteristics are inferior to those of alloys with controlled amounts of other elements.

Wrought Alloys. Binary alloys of high purity, containing as much as 10% Cu, have been successfully rolled, on a small scale, but since the difficulty of working increases with increase in copper content, the upper limit for practical production would be 5 to 6%. However, the commercial alloys ordinarily contain a nominal amount of not more than 4½% Cu with additions of manganese, magnesium or silicon. Such alloys belong to the important group generally known as "duralumin".

Heat Treatment. The solubility of copper in solid aluminum is 5.65% at the eutectic temperature (1018 F), and decreases to less than ¼% at room temperature. For this reason the aluminum-copper alloys are susceptible to age hardening. A solution treatment at a temperature in the range from 900 to 975 F puts most of the soluble copper into solution. Quenching from this temperature produces a supersaturated solid solution from which some precipitation occurs in finely dispersed form during natural aging

* Assistant Director of Research, Aluminum Research Laboratories, New Kensington, Pa.
* Aluminum Company of America, Pittsburgh

after quenching, with the result that the strength and hardness increase and the elongation decreases. Additional precipitation, producing a further increase in strength and hardness, may be obtained by artificial aging in the temperature range from 300 to 400 F. In the commercial alloys, the addition of magnesium greatly increases the strength

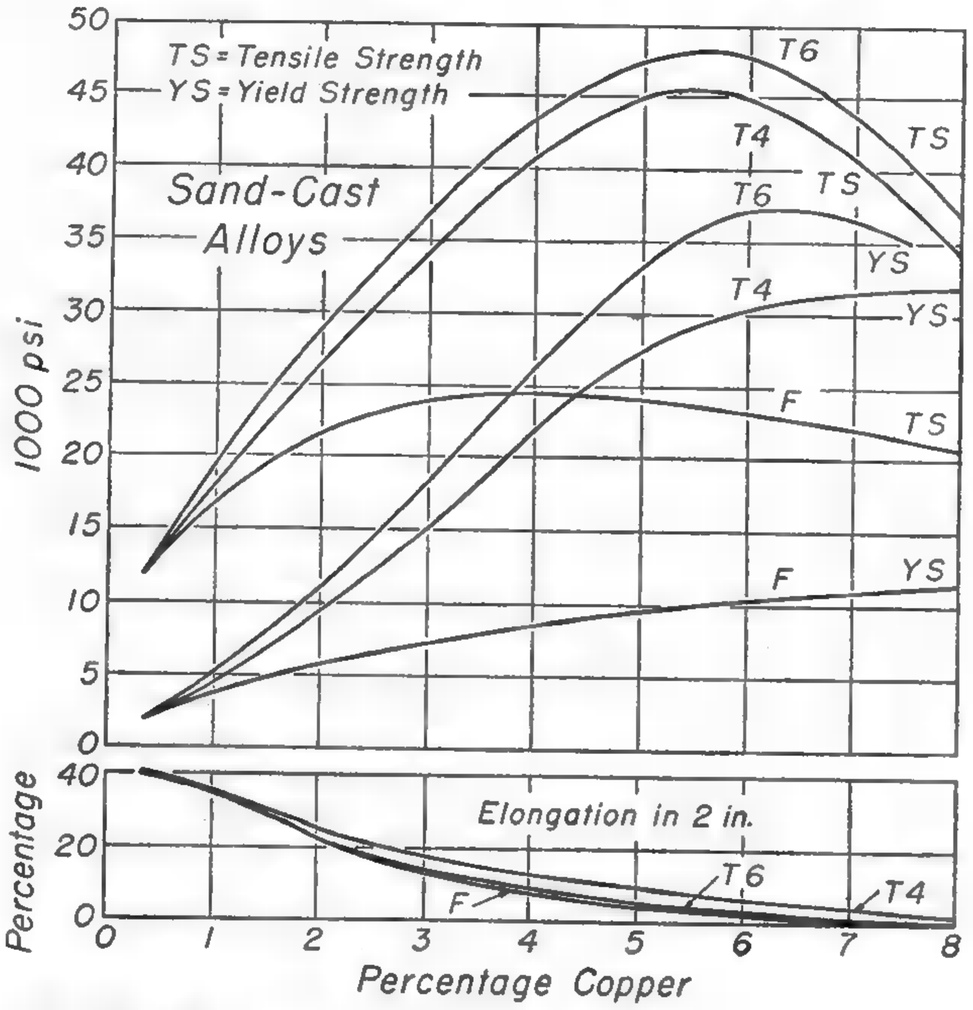

Fig. 1 Tensile properties of sand-cast aluminum-copper alloys of high purity. Tensile specimens cast to size, ½ in. in diam at reduced sections. *F*, as cast; *T4*, quenched in water after solution treatment at high temperature; *T6*, precipitation hardened after solution treatment.

obtainable as a result of heat treatment, and the addition of silicon increases the response to artificial aging. In one important commercial alloy the response to artificial aging is increased by cold work after the solution heat treatment.[1]

Mechanical Properties. The strictly binary aluminum-copper alloys are of little commercial importance, but the effect of copper as an alloying element can best be shown by a study of the properties of high-purity binary alloys.

The mechanical properties of high-purity aluminum-copper alloys are shown in Fig. 1, according to data obtained by testing sand-cast specimens;[2] and in Fig. 2, according to data obtained by testing specimens cut from rolled sheet.[2] From these curves, the effect of thermal treatments as well as of copper content can be seen. Additions of approximately 6% Cu give the maximum benefit of copper to the heat treated alloys.

Endurance Limit. The rotating-beam endurance limit (500 million cycles) of the aluminum-copper alloys increases with increase in copper content and, for a given alloy, is increased by solution heat treatment. Little if any improvement is obtained by subsequent artificial aging.[7]

Other Characteristics. *Density.* As would be expected, the densities of both the solid and liquid aluminum-copper alloys increase with the copper content. At 68 F the density of the sand-cast alloy containing 4% Cu is about 2.77 g per cu cm, and that of the 8% Cu alloy is about 2.86 g per cu cm. At 1290 F the densities for these alloys are, respectively, about 2.44 and 2.53 g per cu cm.[3]

Electrical and Thermal Conductivity. The electrical and thermal conductivities of aluminum are reduced by copper, an effect that is greater when the copper is in solid solution. For example, the electrical conductivity at 68 F is reduced from about 65% that of the standard annealed copper to about 37% for an alloy with about 5½% Cu quenched from a solution treatment.[4] The corresponding values for thermal conductivity are 0.57 and 0.35 cgs units.

Thermal Expansion. The coefficients of thermal expansion of aluminum-copper alloys decrease continuously with increasing copper content from about 0.000024 per °C (68 to 212 F) for pure aluminum to about 0.000020 for the 33% Cu alloy. The rate of decrease is greatest from 0 to 8% Cu.[5]

Lattice Parameter.[6] The aluminum-copper alloys, like pure aluminum, have a face-centered cubic lattice. The lattice parameter is decreased from 4.0413 for pure aluminum to 4.0305 × 10^{-8} cm for about 5% Cu in solid solution.

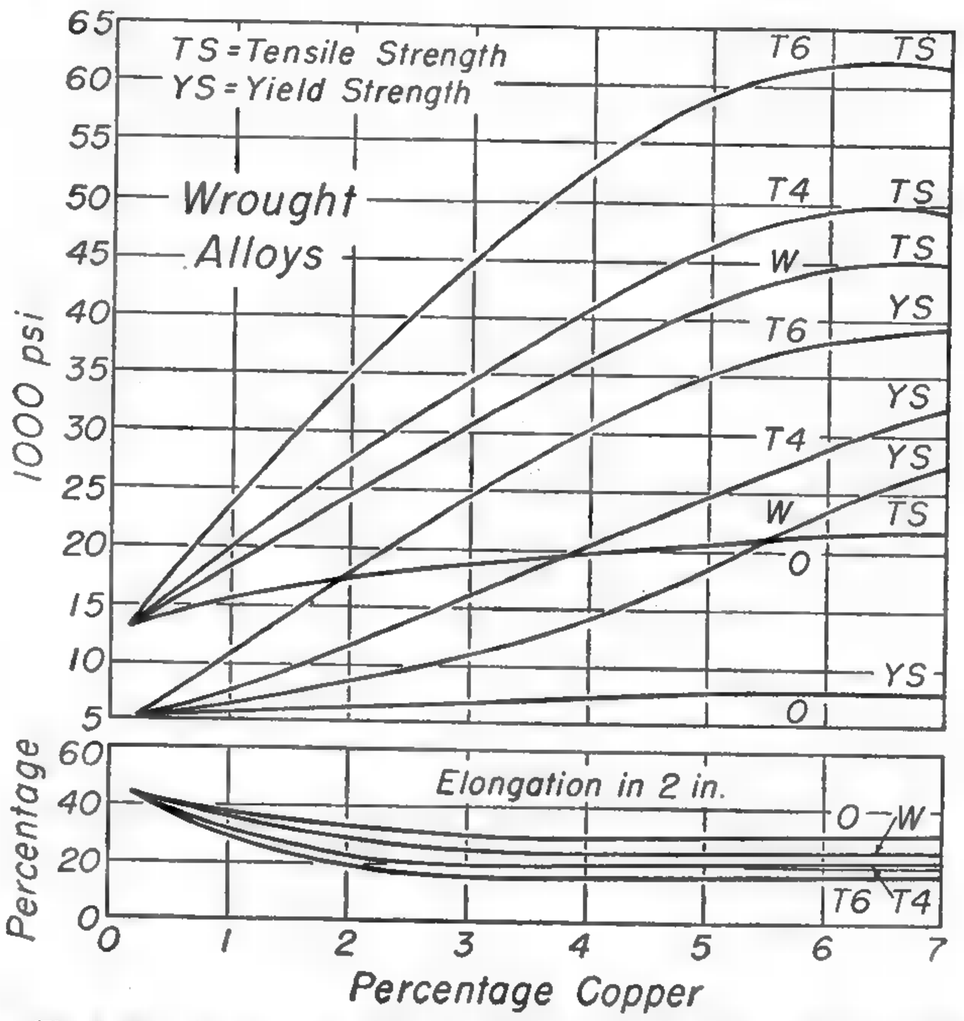

Fig. 2 Tensile properties of wrought aluminum-copper alloys of high purity. Standard ½-in. specimens from sheet $\frac{1}{16}$ in. thick. *O*, annealed; *W*, tested immediately after quenching in water from a solution heat treatment; *T4*, as in *W* but subsequently aged at room temperature until no further changes in properties were perceptible; *T6*, as in *T4*, followed by precipitation treatment at elevated temperature.

Resistance to Corrosion. The addition of more than about ¼% Cu lowers the high resistance of pure aluminum to corrosion. The resistance to corrosion of the aluminum-copper alloys is generally lower than that of the aluminum-silicon, aluminum-manganese, aluminum-magnesium and aluminum-magnesium silicide alloys, but is satisfactory for most applications, especially in relatively thick sections, as in castings.[8] Thin sheets of aluminum-copper alloy generally require protective coatings to resist severely corrosive conditions. The most effective protection is that obtained by the use of corrosion-resistant aluminum or aluminum alloy coatings which protect exposed areas of the core cathodically as in alclad products.

The resistance to corrosion may be affected greatly by heat treatment; the maximum resistance to corrosion of thin sections is obtained by a rapid quench and natural aging. Artificial aging or other reheating of thin sections of aluminum-copper alloys may reduce markedly the resistance to corrosion, although in heavy sections where rapid quenching is not possible, artificial aging generally improves the resistance to corrosion.

Properties of Aluminum-Silicon Alloys

By L. W. Kempf*

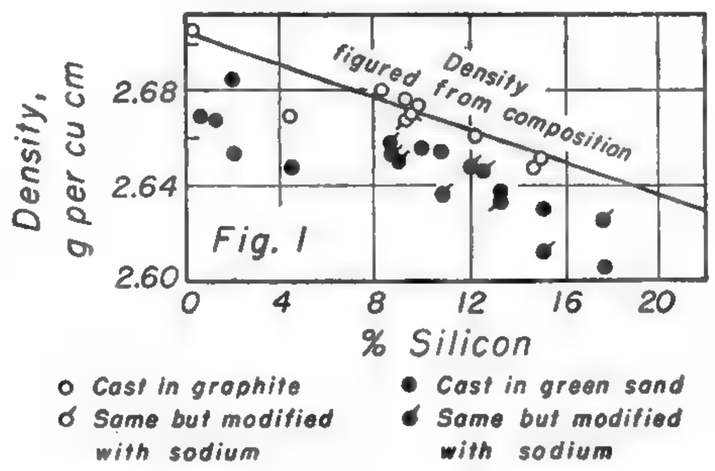
SILICON probably stands second to copper in importance as an ingredient in aluminum casting alloys. Attention was directed to the many advantageous properties of these alloys in 1921 when A. Pacz[1] discovered a method of modifying their structure and thus improving their tensile properties by treating the molten alloy with small amounts of sodium fluoride immediately before casting.[2,3] Probably the most generally valuable properties of the aluminum-silicon alloys are their excellent casting qualities, including superior fluidity and freedom from hot shortness. The strength and hardness obtained in the binary alloys are not at all remarkable. Other advantages of the silicon alloys are high resistance to corrosion, low specific gravity, low thermal expansion and high conductivity for heat and electricity. The chief use of the binary alloys is in castings containing about 5 to 13% Si.

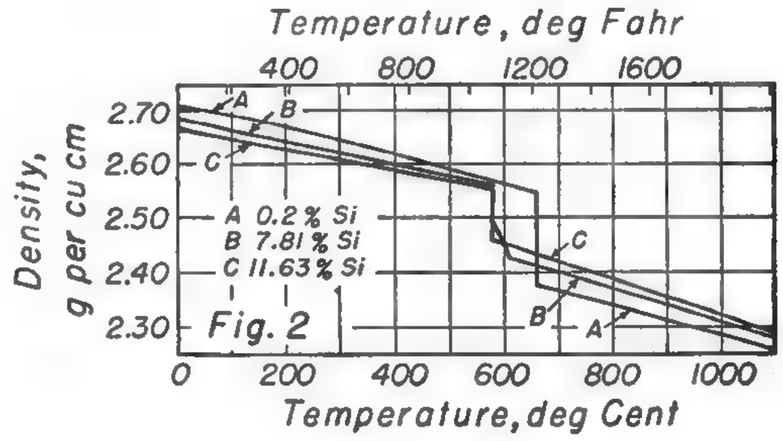
Density of Solid Alloys. Edwards[4] has determined the density of alloys containing as much as 18% Si. The diagram in Fig. 1 presents his data. These numerical values are approximately equal to the specific gravity. The influence of temperature on the density of alloys containing 0.2, 7.81 and 11.63% Si is given in Fig. 2.

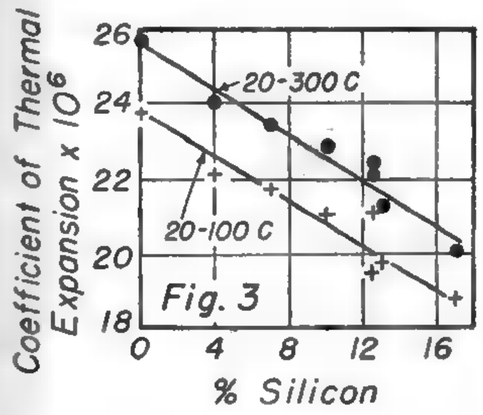
Thermal Expansivity. The coefficient of thermal expansion of silicon is less than one third that of aluminum, and the aluminum-silicon alloys have appreciably lower expansivity than pure aluminum. The variation in coefficient of expansion with silicon content is indicated in Fig. 3.

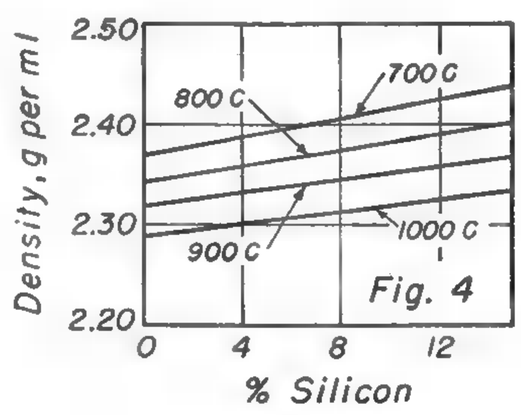
Growth. The solubility of silicon in solid aluminum varies with temperature from about 0.05% at 200 C (390 F) to 1.65% at 577 C (1070 F). Alloys quenched from a high-temperature solution treatment are of appreciably higher density than the same alloys in equilibrium at room temperature. The magnitude of this difference in density is small under all conditions but is greater the higher the degree of supersaturation. Thus with ordinary sand castings the rate of cooling is such that for all practical purposes, and especially for uses involving temperatures below 200 F, no changes can be detected. Changes in density have been estimated by measuring the linear change in dimensions accompanying reheating to elevated tempera-

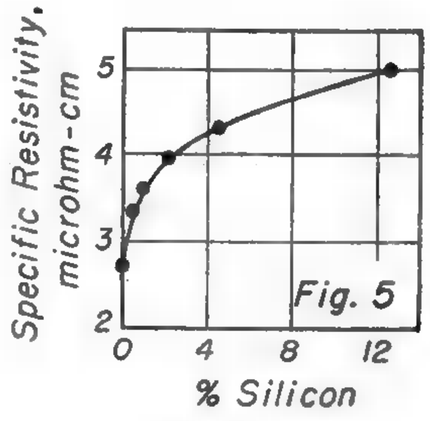
* Deceased

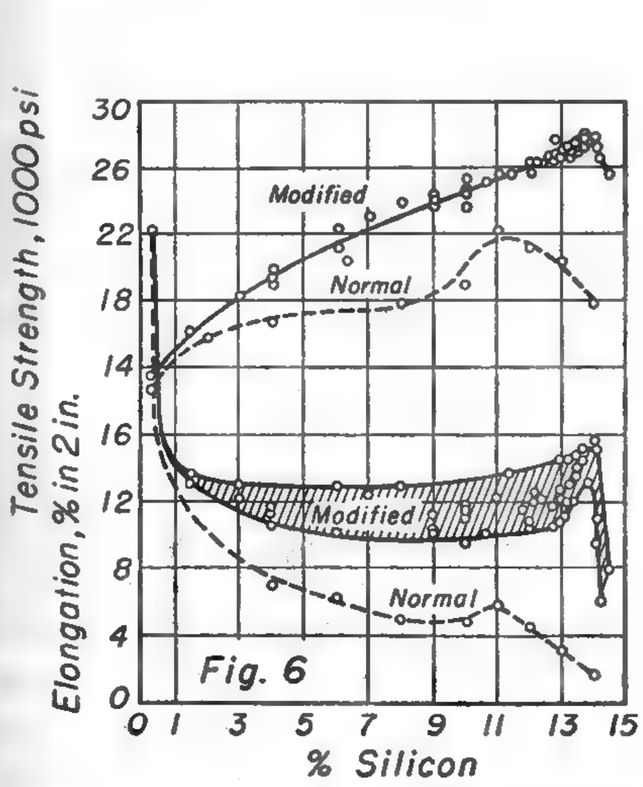


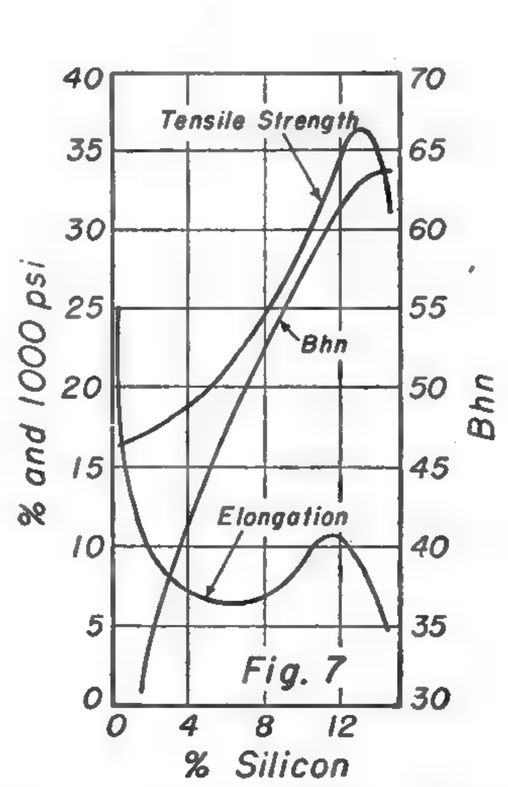












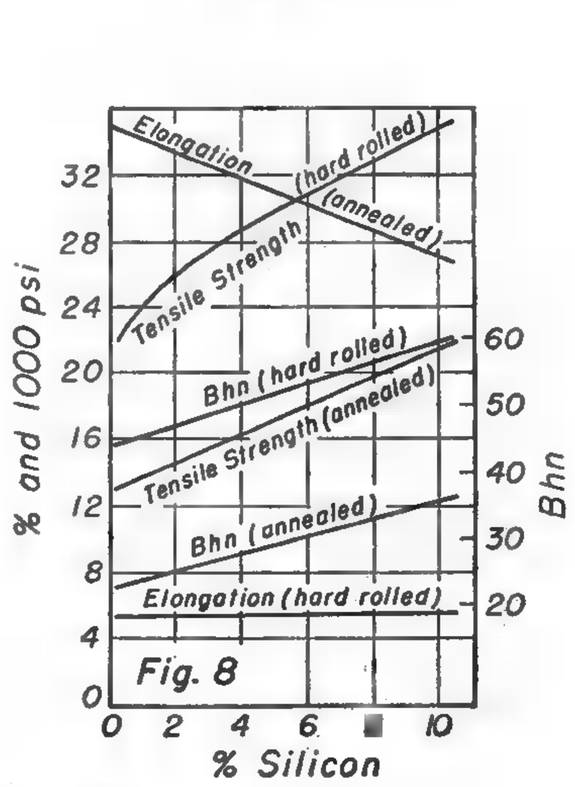


Fig. 1 to 8 Some physical and mechanical properties of aluminum-silicon alloys

tures of alloys quenched from high-temperature solution treatments. This change in dimension has been termed "growth" or "permanent growth". The maximum amount of growth observed in alloys containing more than about 1.7% Si quenched from near the eutectic temperature corresponds to a unit change of 0.0016 in lineal dimensions. Heating for 10 to 20 hr at 400 to 450 F is required to bring about equilibrium as regards growth. The time for attainment of equilibrium varies inversely with temperature in a logarithmic manner.

Density of Liquid Alloys. The density of liquid alloys, as determined by Edwards, is given in Fig. 4.

Solidification Shrinkage. The percentage of change in volume from a liquid at the melting point to a solid at the freezing point is known as "solidification shrinkage". Edwards gives the solidification shrinkage of pure aluminum as 6.6%, that of an alloy of 7.81% Si as 5.6%, and of an alloy of 11.63% Si as 3.8%. The change in solidification shrinkage with silicon content is illustrated in Fig. 2.

Pattern Shrinkage. The pattern shrinkage is usually determined by casting a straight cylindrical bar between a pair of graphite or metal plates that are rigidly maintained a known distance apart, and measuring the length of the bar when cold. Determinations by Edwards on alloys containing 12.55% and 22.4% Si give a shrinkage of 0.16 and 0.15 in. per ft respectively. The usual pattern shrinkage used in aluminum foundries for all aluminum alloys is $\frac{5}{32}$ in. (0.156 in.) per ft.

Electrical Resistivity. Increasing amounts of silicon increase the electrical resistivity of aluminum-silicon alloys, as indicated in Fig. 5. These data are from measurements by J. D. Edwards on sand-cast specimens. Some measurements by C. S. Taylor on high-purity alloys in wrought form are given in Table I.

Table I. Electrical Resistivity of High-Purity Aluminum-Silicon Alloys

Iron and Copper Less Than 0.05%

Silicon, percentage	Resistivity, microhm-cm[a]	Resistivity, microhm-cm annealed[b]
0.02 or less	2.68	2.68
0.06	2.778	2.778
0.14	2.847	2.770
0.16	2.860	2.769
0.23	2.947	2.776

[a] Heated 2 days at 495 C (925 F) and quenched in cold water.
[b] Heated 2 days at 495 C, quenched in cold water, and then annealed 100 days at 200 C.

Thermal Conductivity. The thermal conductivity of aluminum-silicon alloys[5] is affected in a marked manner, especially at high contents of silicon, by the particle size and distribution of the silicon. The smaller the particles of silicon, the higher the conductivity. The conductivity of sand castings in the condition of highest conductivity (annealed) decreases from about 0.39 cgs units for the 5% Si alloy to about 0.31 cgs units for the 13% Si alloy. Modification of the 13% Si alloy with sodium increases the conductivity to 0.39 cgs units. Similarly, the chill-cast 5% Si alloy, by virtue of its fine structure, has a conductivity of about 0.44 cgs units.

Elastic Properties. The yield strengths of aluminum-silicon alloys are generally lower than those of aluminum-copper alloys of approximately the same tensile strength. This characteristic of the silicon alloys limits their use in some applications, but it is an advantage in others where some slight bending or forming operations must be carried out on castings. Few reliable data have been published concerning the elastic limit, but isolated determinations and general experience would place the true elastic limit of all aluminum-silicon alloy sand castings containing as much as 14% Si, at not over 3000 psi. The yield strength of modified sand castings varies from about 10,000 psi at 8% Si to 12,000 psi at 14% Si. A typical yield point for the normal sand-cast 5% Si alloy is about 9000 psi. According to the determinations of Templin and Paul,[6] the addition of silicon to aluminum results in a fairly uniform increase of Young's modulus in tension from about 10,250,000 psi for the 5% Si alloys to about 11,100,000 psi for an alloy containing 13% Si.

Tensile Properties. Figure 6 gives the tensile properties of both normal and modified aluminum-silicon alloys in the form of sand-cast test bars ½ in. in diam.[2] These values represent laboratory determinations and the values given for modified alloys are those for material in which special care was taken to obtain the optimum effects of the modification process. Figure 7 indicates the variation in tensile properties with silicon content of chill-cast test bars.[7] Figure 8 gives the tensile properties of aluminum-silicon sheet, 0.08 in. thick, in the hard rolled and annealed conditions.

Fatigue Resistance. As given in the literature, endurance limits for cast aluminum-silicon alloys containing from 5 to 14% Si vary between 5700 psi and 9500 psi. Results are not concordant and the determinations were made on the basis of 5 to 50 millions of reversals. Determinations made in the Aluminum Research Laboratories on the basis of 500,000,000 cycles, with the R. R. Moore type of rotating-beam machine, place the endurance limit of the normal sand-cast 5% Si alloy at about 6500 psi. The value for the modified 13% Si alloy is about 6000 psi.

Corrosion Resistance. Comparative experience in various fields indicates that the aluminum-silicon alloys preserve a better appearance under the conditions of ordinary atmospheric corrosion than do the aluminum-copper alloys. The rate of loss in mechanical strength of either of the types of alloys under these conditions is very low. Under conditions of salt spray corrosion, aluminum-silicon alloys appear to be definitely superior to the aluminum-copper alloys or the aluminum-copper-zinc alloys. However, they are inferior to the aluminum-magnesium alloys under these conditions. Czochralski[8] presents data on relative loss in weight, in steam and nitric acid, of the modified 13% Si alloy, the 8% Cu alloy, and the 12% Zn-2% Cu alloy. All alloys were in the cast condition. Under these conditions the 13% Si alloy is superior to the 8% Cu, and the 12% Zn-2% Cu alloys.

Casting Properties. The aluminum-silicon alloys are especially fluid, fill molds better, and take sharper impressions than any of the other common alloys of aluminum. For the normal alloys, the fluidity increases with silicon content until this content reaches the composition of the eutectic, about 11.6% Si, and about 12 to 14% Si for the modified alloys. Alloys unusually free from hot shortness are those containing more than about 3% Si along with iron and copper in concentrations common in ordinary commercial virgin ingot. This valuable property improves with increasing silicon content until the eutectic composition is reached, but all the alloys containing from 5 to 13% Si can be cast readily without cracking. The 5% Si alloy is comparatively easy to feed, but as the silicon increases, the alloys become subject to a peculiar type of internal shrinkage, and careful feeding is necessary with alloys of high silicon contents. The ratio of volume of risers to volume of castings should, in general, be greater in the use of the 13% Si alloys than in the use of the 8% Cu alloy. Because of freedom from hot shortness and because of the characteristic tendency to form a sound outer layer or skin, the aluminum-silicon alloys are especially suitable for the production of castings that must be free from leaks.

Welding Rod. Some of the properties that make the aluminum-silicon alloys so valuable in the castings field have also been responsible for their wide use as welding rod. An alloy containing about 5% Si is widely used for welding both cast and wrought products. Such rod is utilized in the cast and wrought forms, depending on the preference of the operator and the type of welding.

Properties of Aluminum-Magnesium Alloys

By W. E. Sicha* and F. Keller*

THE binary alloys of aluminum with magnesium attracted the interest of investigators as early as 1900. There have been numerous attempts to utilize for general purposes alloys containing as much as 10% Mg; alloys containing up to 30% Mg have been used for special purposes.

The aluminum-magnesium alloys are lighter than aluminum, have good physical properties, excellent resistance to corrosion and are easily machined. Certain fabricating difficulties encountered initially have been overcome and commercial exploitation of these alloys has progressed at a moderate rate.

Density. The densities of solid aluminum-magnesium alloys decrease continuously with magnesium content, as indicated by the curve of Fig. 1.

Thermal Expansivity. The coefficient of thermal expansion of magnesium is somewhat higher than that of aluminum, and the expansivity of aluminum-magnesium alloys increases with magnesium content according to Fig. 2.

Growth. The precipitation of magnesium constituent from a supersaturated aluminum solid solution is accompanied by a slight decrease in density. An alloy containing 10% Mg in solid solution showed a change in density corresponding to a unit linear expansion of 0.0015 after heating to approximately 400 F for a sufficient period of time to bring about complete stabilization.

Electrical and Thermal Conductivity. The electrical conductivity of aluminum decreases continuously with increasing magnesium content, as shown by Fig. 3. Determinations on which this curve was based were made on alloys quenched from a solution treatment at high temperature. Alloys treated so as to contain a minimum amount of magnesium in solid solution would ordinarily have appreciably higher electrical conductivities than this curve indicates.

A knowledge of the general relationship between electrical and thermal conductivity of aluminum alloys permits the estimation of thermal conductivity from electrical conductivity, as indicated in Fig. 3.

Casting Characteristics. Alloys containing as much as 5% Mg may be cast in ordinary green sand molds. When so cast, especially in heavy sections, alloys with magnesium concentrations greater than this may develop a dark, porous outer ring. The alloys form considerable dross when molten, a tendency that increases with magnesium content. These difficulties have been overcome successfully for commercial purposes, by the development of foundry technique. Inherently the aluminum-magnesium alloys are not particularly difficult to cast, since they are quite fluid and not especially hot short. Very little difficulty from cracking has been encountered in the relatively large castings. Pressure-tight castings are less easily obtained with the aluminum-magnesium than with the aluminum-silicon alloys.

Tensile Properties and Hardness of Sand Castings. The variation with magnesium content in mechanical properties of sand-cast aluminum-magnesium alloys is shown in Fig. 4.

The variation in solid solubility of magnesium in aluminum, from about 15% at the eutectic temperature of 451 C to less than 4% at room temperature, renders some of the alloys susceptible to improvement in tensile properties by heat treatment. The curves of Fig. 5 show the variation with magnesium content, in tensile properties and hardness of heat treated sand castings. These properties were attained with solution heat treated ½-in. diam test bars of low-impurity-content alloys, cast in green sand. Comparison of the curves of Fig. 4 with those of Fig. 5 indicates that heat treatment brings about a profound change in the properties of alloys containing more than 6% Mg.

Working Characteristics. Alloys containing as much as 2 or 3% Mg can be reduced from cast ingots by forging or rolling with little difficulty. When alloys contain more than about 3% Mg, breaking down cast ingots becomes increasingly difficult. This condition has precluded the commercial development and application of wrought alloys containing more than about 6% Mg.

Properties of Wrought Alloys. Figure 6 shows the change in tensile properties and hardness of aluminum-magnesium alloys with variation in the magnesium content. For alloys containing as much as 10% Mg, the data from which Fig. 6 was derived were obtained from forged bars. For more than 10% Mg the material from which the test specimens were taken was produced by extrusion. The specimens had been solution heat treated and the alloys were of high purity. It will be noted that tensile strength increases to a maximum at about 15% Mg, which is approximately the maximum solubility of magnesium in solid aluminum. As the magnesium content increases beyond this concentration, the tensile strength decreases quite rapidly. Brinell hardness and yield strength increase continuously with magnesium content. A relatively constant elongation of about 32% is noteworthy between 2 and 12% Mg.

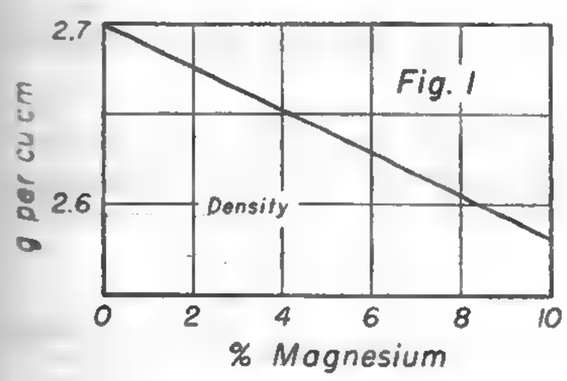

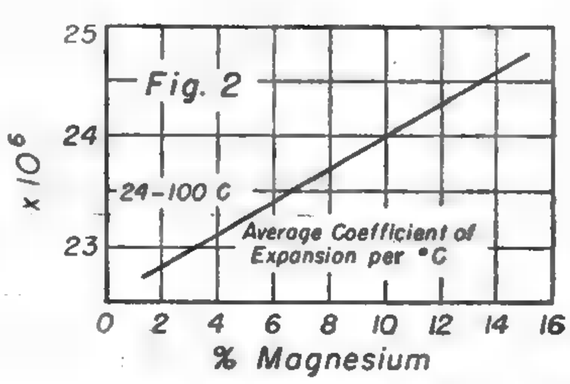

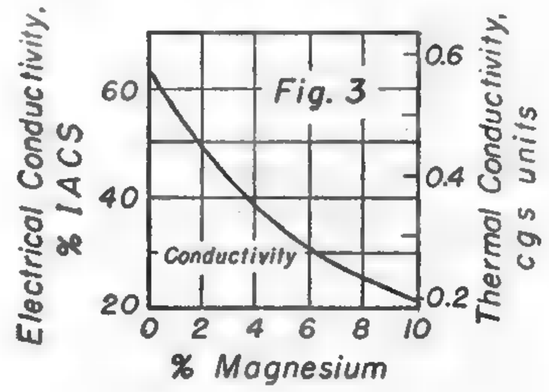

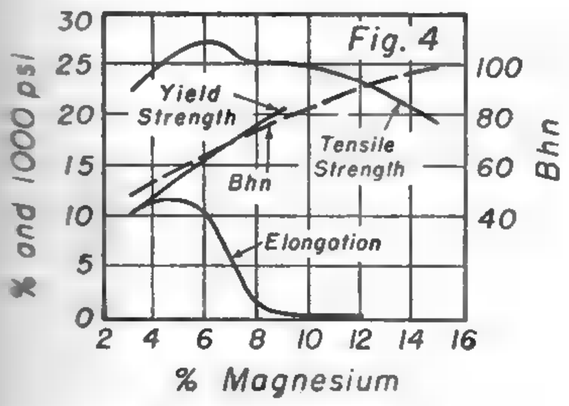

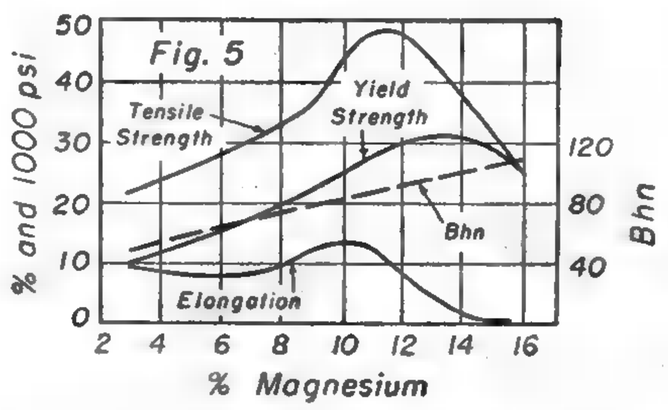

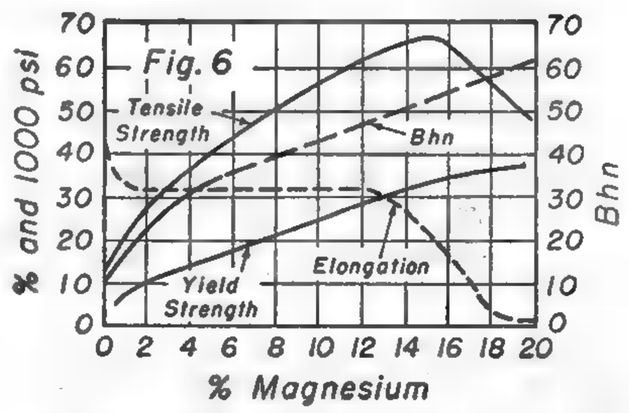

Fig. 1 to 6 Some physical and mechanical properties of aluminum-magnesium alloys

Fatigue Resistance. In wrought aluminum the endurance limit, based on 500,000,000 reversals of stress, is increased with magnesium content from about 5000 psi at 0 Mg to about 20,000 psi at 6% Mg. With greater concentrations of magnesium the rate of increase is much slower; the 10% Mg alloy has an endurance limit of about 21,000 psi. The aluminum-magnesium alloys have a higher ratio of endurance limit to tensile strength than the aluminum-silicon, aluminum-copper or aluminum-zinc alloys.

Properties at Elevated Temperatures. As indicated in Fig. 7 and 8 for sand castings of a 4% and a 10% Mg alloy respectively, tensile properties of these alloys at elevated temperatures are higher than those of alloys of the aluminum-silicon or aluminum-zinc systems but generally not so high as the corresponding aluminum-copper alloys. The data on which these curves are based were determined by testing specimens cast to size in green sand and heated at the temperature of testing, long enough to bring about complete stabilization.

Resistance to Corrosion. The cast aluminum-magnesium alloys display excellent resistance to corrosion, both in the atmosphere and in salt spray. This resistance to corrosion is of a different order of magnitude from that of casting alloys of the aluminum-silicon, aluminum-copper, or aluminum-zinc systems. The aluminum-magnesium alloys generally preserve a better appearance and suffer less loss in mechanical properties than the more common casting alloys. As in most aluminum alloys, the presence of impurities markedly reduces resistance to corrosion.

The wrought alloys also, in the compositions being produced commercially in this country, have excellent resistance to corrosion.

The aluminum-magnesium alloys are the most resistant to alkaline corrosion of any of the aluminum alloys; resistance increases with magnesium content.

Temper Designations for Aluminum Alloys

For a generation the various tempers of commercial wrought aluminum alloys have been designated by a system of numbers and letters (-1/2H, -W, -T, -RT, and others).* More recently a comprehensive system, applicable to both cast and wrought products, was developed and applied to all tempers of cast products and to some tempers of certain new wrought products.

Metallurgical advances during the past several years have revealed inadequacies in the temper designations that have been used for wrought alloys. Consequently, beginning in October 1947, the more comprehensive system of nomenclature, recently revised, is being applied to both cast and wrought products. In this system, provision is made for developments that may come in the future. This revised system has been used fully in the ALUMINUM SECTION of the present edition of this Handbook.

The principle of the system of nomenclature for cast and wrought products remains the same; that is, the temper designation, where required, follows the alloy designation and is separated from it by a hyphen. The temper designation consists of a letter indicating the basic temper, which may be defined more specifically by the addition of one or more digits. No changes have been made in the temper designations for cast products.

The general scheme of the system of nomenclature is:

- **-F** As fabricated
- **-O** Annealed, recrystallized (wrought products only)
- **-H** Strain hardened
  - -H1, plus one or more digits — Strain hardened only
  - -H2, plus one or more digits — Strain hardened and then partial annealed
  - -H3, plus one or more digits — Strain hardened and then stabilized
- **-W** Solution heat treated—unstable temper
- **-T** Treated to produce stable tempers other than -F, -O, or -H
  - -T2 Annealed (cast products only)
  - -T3 Solution heat treated and then cold worked
  - -T4 Solution heat treated
  - -T5 Artificially aged only
  - -T6 Solution heat treated, then artificially aged
  - -T7 Solution heat treated, then stabilized
  - -T8 Solution heat treated, cold worked, and then artificially aged
  - -T9 Solution heat treated, artificially aged, and then cold worked
  - -T10 Artificially aged and then cold worked

More detailed information concerning the designations is given in the Explanatory Notes that follow the Conversion Tables I and II.

* EDITOR'S NOTE. These temper designations for aluminum alloys were developed by the Aluminum Company of America. The revised system of nomenclature described here has also been developed by the Aluminum Company of America, and is used in this section of Metals Handbook to designate the various tempers of the alloys for which this company has compiled data.

Table I. Temper Designations for Strain Hardened Wrought Aluminum Alloys That Are Not Heat Treatable[a]

Old Temper Designation	New Temper Designation[b]: Strain Hardened Only	Strain Hardened and Then Partial Annealed	Strain Hardened and Then Stabilized
	Alloys 2S and 3S		
¼H	-H12	-H22	
½H	-H14	-H24	
¾H	-H16	-H26	
H	-H18	-H28	
Extra Hard (Not Standard)	-H19		
	Alloys 4S, 52S and 56S[c]		
¼H			-H32
½H			-H34
¾H			-H36
H			-H38
Extra Hard (Not Standard)			-H39

(a) Alloys listed are also available in -O and -F tempers.
(b) The tempers shown are standard for the alloys listed.
(c) The alloys 4S, 52S and 56S may also be obtained in the -H1 and -H2 type conditions.

Table II. Temper Designations for Heat Treated Wrought Aluminum Alloys

A, heat treated by the producer. C, heat treated by the manufacturer of the finished product. D, driven rivets.

(a) Products listed are available also in -O and -F tempers. (b) Forgings are available also in -F temper. (c) For extruded tubing see columns for extrusions. (d) Boiling water quench. (e) Driven cold after full natural aging. (f) Driven cold immediately after solution heat treament, or when refrigerated to defer natural aging. (g) Driven hot, at the solution heat treating temperature. (h) To be specific, the time of natural aging must be stated—for example, 75 S-W (2 hr), 75 S-W (2 months). (i) Available only in sheet and plate.

Explanatory Notes

-F **As Fabricated.** This designation applies to products that acquire some temper qualities in the shaping processes but are not subsequently thermally treated or intentionally strain hardened.

-O **Annealed, Recrystallized.** This designation applies to the softest temper of wrought alloy products.

-H **Strain Hardened.** This designation applies to products that have their strength increased by strain hardening, with or without supplementary thermal treatments to produce partial softening. The -H is always followed by two or more digits. The first digit indicates the specific combination of basic operations, and the final digit or digits, the final degree of strain hardening.

Subdivisions of the -H Temper

-H1 *Strain Hardened Only.* The number following this designation indicates the degree of strain hardening. Thus, 2S-¼H (strain hardened only) becomes 2S-H12, and a temper intermediate between -¼H and -½H would be designated -H13.

-H2 *Strain Hardened and Then Partial Annealed.* The number following this designation indicates the degree of strain hardening remaining after the product has been partial annealed. Thus, 2S-½H (strain hardened and partial annealed) becomes 2S-H24.

-H3 *Strain Hardened and Then Stabilized.* The number following this designation indicates the degree of strain hardening remaining after the product has been strain hardened a specific amount and then stabilized. Thus 52S-½H (strain hardened and stabilized) becomes 52S-H34.

-W **The Unstable Condition Following Solution Heat Treatment.** This designation, because of natural aging, is specific only when the period of aging is indicated, for example 24S-W (½ hr), 75S-W (2 months).

-T **Treated to Produce Stable Tempers Other Than -F, -O, or -H.** This designation applies to products treated thermally to produce stable tempers with or without supplementary strain hardening. The -T followed by the numerals 2 to 19 inclusive designates one specific combination of basic operations (61S-T6). Should some other variation of the same basic operations be applied to the same alloy, *resulting in different characteristics,* then other digits are added to the basic designation (61S-T61 or 61S-T62). A period of natural aging at room temperature may occur between or after the operations listed. This period is controlled when it is metallurgically important.

Subdivisions of the -T Temper

-T2 *Annealed.* (Cast products only.) This designation applies to castings annealed for such purposes as improving ductility and increasing dimensional stability (142-T21).

-T3 *Solution Heat Treated and Then Cold Worked.* This designation applies to products that are cold worked chiefly to increase the strength (24S-RT becomes 24S-T36), and also applies to products in which the effect of cold work, such as flattening, is recognized in specifications. (Mill heat treated 24S-T flat sheet becomes 24S-T3.)

-T4 *Solution Heat Treated and Naturally Aged to a Substantially Stable Condition.* This designation applies when the product is not cold worked after heat treatment (24S-T sheet, heat treated by the customer, becomes 24S-T4), and also when applicable specifications do not recognize the effect of cold work in flattening and straightening operations. (Mill heat treated 61S-W flat sheet becomes 61S-T4.)

-T5 *Artificially Aged Only.* This designation applies to products that are artificially aged without prior solution heat treatment. The artificial aging of these products improves mechanical properties (53S-T5 extrusions), and dimensional stability (A132-T551 cast pistons).

-T6 *Solution Heat Treated and Then Artificially Aged.* This designation applies to products that are not cold worked after solution heat treatment and in which the effect, if any, of flattening or straightening is not recognized in applicable specifications. (Whether flattened or not, 61S-T becomes 61S-T6, and 14S-T becomes 14S-T6.)

-T7 *Solution Heat Treated and Then Stabilized.* This designation applies to products in which the temperature and time conditions for stabilizing are such that the alloy is carried beyond the point of maximum hardness, providing control of growth or residual stress or both (355-T71).

-T8 *Solution Heat Treated, Cold Worked, and Then Artificially Aged.* This designation applies when the cold working is done for improving strength (11S-T8, Alclad 24S-T86), and also when the cold working effect of flattening is recognized in specifications (Alclad 24S-T81 flat sheet).

-T9 *Solution Heat Treated, Artificially Aged, and Then Cold Worked.* (The cast bearing formerly designated "XA750-T6 cold worked approximately 4%" becomes XA750-T91.)

-T10 *Artificially Aged and Then Cold Worked.* (The cast bearing formerly "750-T5 cold worked 4%" becomes 750-T101.)

PROPERTIES OF ALUMINUM AND ALUMINUM ALLOYS

Aluminum (99.996 Al)*

C *1 Density*
at 20 C (68 F). 2.6989 g per cu cm (0.09751 lb per cu in.)
at 25 C (77 F). 2.6978 g per cu cm (0.09747 lb per cu in.)
D *2 Melting point.* 660.2 C (1220.4 F)
4 Boiling point. 2060 C (3740 F)
6 Thermal expansion.
20 to 100 C (68 to 212 F). 0.00002386 per °C
20 to 200 C (68 to 392 F). 0.00002458 per °C
20 to 300 C (68 to 572 F). 0.00002545 per °C
20 to 400 C (68 to 752 F). 0.00002649 per °C
20 to 500 C (68 to 932 F). 0.00002768 per °C
11 Specific heat at 100 C (212 F). 0.2226 cal per g
13 Latent heat of fusion. 94.6 cal per ■
18 Heat of combustion. 7389 cal per g
E *1 Volume conductivity* referred to standard copper. 64.94%
2 Electrical resistivity at 20 C (68 F). 2.6548 microhm-cm
5 Temperature coefficient of electrical resistivity at 20 C (68 F). 0.00429 per °C
F *1 Reflectivity.* 90%, for light from tungsten filament; 85%, at $\lambda = 2500$ A; 95%, at $\lambda = 10{,}000$ A
5 Emissivity at 25 C (77 F). 0.030 in air
G *2 Mass magnetic susceptibility.* 0.6×10^{-6} cgs
J *1 Crystal structure.* Face-centered cubic; $a = 4.0413$ kX
K *Mechanical Properties.*

Condition	Tensile Strength, psi	Yield Strength, psi	Elongation,(a) percentage	Brinell Hardness Number(b)
Annealed	6,875	1,775	48.8	17
Cold rolled 75%	16,300	15,425	5.5	27

(a) Sheet specimens, $\frac{1}{16}$ in. thick (b) 500-kg load, 10-mm ball

Aluminum (99.0+ Al)*

A *1 Common name.* Commercially pure aluminum
2 Trade name. 2S alloy
3 ASTM number. B 209–46T, Alloy A2 (sheet and plate); B 211–46T, Alloy A2 (bar, rod and wire)
4 Government number. QQ-A-561 (sheet and plate); QQ-A-411 (bar, rod, shapes and wire); WW-T-783 (tubing)
6 Foreign equivalents. British BS 2L4 (hard); BS 2L16 (half hard); BS 2L17 (soft) (sheet and plate); BS L34 (bar, rod and shapes); BS L36 (wire)
B *1 Typical uses.* Applications where very good formability or very good resistance to corrosion, or both, are required, and where high strength is not necessary. Cooking utensils, food- and chemical-handling and -storage equipment, bottle and jar closures, and various architectural components are typical.
C *1 Density* at 20 C (68 F). 2.71 g per cu cm (0.098 lb per cu in.)
5 Solidification shrinkage. 6.6%
D *1 Liquidus temperature.* 657 C (1215 F)
2 Solidus temperature. 643 C (1190 F)
6 Thermal expansion (condition O).
−60 to + 20 C (−76 to + 68 F). 0.0000217 per °C
20 to 100 C (68 to 212 F). 0.0000235 per °C
20 to 200 C (68 to 392 F). 0.0000246 per °C
20 to 300 C (68 to 572 F). 0.0000256 per °C
11 Specific heat at 100 C (212 F). 0.2297 cal per g
12 Heat content and specific heat versus temperature.

Temperature, deg Cent	Temperature, deg Fahr	Heat Content, Btu per lb	Heat Content, cal per g	Specific Heat, mean, 0° to T°	Specific Heat, at T°

(a) J. F. Shadigen, Heat-Temperature Curves of Metals, Iron Age, 110, 218 (1922)

13 Latent heat of fusion. 93.0 cal per ■
16 Thermal conductivity at 25 C (77 F). 0.53 cal/sq cm/cm/°C/sec, condition O; 0.52 cal/sq cm/cm/°C/sec, condition H18
18 Heat of combustion. 7400 cal per g
19 Recrystallization temperature. 290 C (550 F) approx, 75% reduction
E *1 Volume conductivity* referred to standard copper. 59%, condition O; 57%, condition H18
2 Electrical resistivity at 20 C (68 F). 2.922 microhm-cm, condition O; 3.025 microhm-cm, condition H18
4 Electrical resistivity (liquid) at 657 C (1215 F). 20.1 microhm-cm
5 Temperature coefficient of electrical resistivity between 10 and 30 C (50 to 86 F). 0.0115 per °C
10 Electrochemical equivalent. 0.09316 mg per coulomb
11 Electrolytic solution potential versus N/10 calomel electrode is 0.83 volts, all tempers (53 g NaCl + 3 ■ H_2O_2 solution).
F *1 Reflectivity.*
As much as 90%, at $\lambda = 5{,}000$ A } depending on surface finish and purity of metal
As much at 87%, at $\lambda = 2{,}500$ A
As much as 97%, at $\lambda = 20{,}000$ A
2 Refractive index. 0.78 to 1.48 in white light
3 Absorptive index. 2.85 to 3.92 in white light
5 Emissivity at 25 C (77 F). 0.035 to 0.06 in air
H *1 Velocity of sound* at 20 C (68 F). 16,300 ft per sec
J *1 Crystal structure.* Face-centered cubic; $a = 4.04$ kX
K *Mechanical Properties. See* Table I.
Strength and elongation at elevated temperatures after prolonged heating at testing temperatures.

Property	Temperature, deg Fahr: 75	300	400	500	600	700
Annealed O						
Tensile strength, psi	13,000	7,500	6000	3500	2500	1500

(a) In general, strengths and elongations are unchanged or improved at low temperatures.
(b) The compressive yield strength is approximately the same as the tensile yield strength. The torsional yield strength is approximately 0.55 times the tensile yield strength. The torsional ultimate strength is approximately 0.65 times the tensile strength.
(c) Sheet specimens, $\frac{1}{16}$ in. thick. (d) Round specimens, ½ in. in diam. (e) 500-kg load, 10-mm ball.
(f) Based on 500,000,000 cycles using R. R. Moore type rotating-beam machine

6 Modulus of elasticity versus temperature.

Temperature, deg Fahr	75	300	400	500	600	700
Approx % of E at 75 F	100	95	90	85	65	40

L *2 Radiography.* Type A or 506 film with no intensifying screen, cardboard exposure holder, 36-in. focal distance, General Electric OX-10 unit, 2.1 H&D film density

Section, in.	Volts	Milliamperes	Time, min
½	65,000	10.0	1.0
1	95,000	6.7	1.0
1½	125,000	5.0	1.0
2	140,000	5.0	1.6

M *Composition Limits. See* Table II.
2 Consequences of exceeding impurity limits. High copper reduces resistance to corrosion.
High iron plus silicon plus manganese reduces formability.
N *1 Melting temperature range.* 675 to 745 C (1250 to 1375 F)
7 Hot working temperature range. 260 to 510 C (500 to 950 F)
10 Maximum reduction between anneals. 70% or more, depending on product
15 Heat treatment. Annealing, 345 C (650 F); holding at temperature is not required.
17 Joining.
Rivet compositions. 2S
Soft solder with Alcoa No. 800; Alcoa No. 61 flux.
Braze with Alcoa No. 717, 43 alloy; Alcoa No. 33 flux; flame either reducing oxyacetylene or reducing oxy-hydrogen.
Atomic-hydrogen weld with 2S alloy; Alcoa No. 22 flux.
Oxyacetylene weld with 2S alloy; Alcoa No. 22 flux; flame neutral.
Metal-arc weld with 2S alloy; Alcoa No. 27 flux.
Carbon-arc weld with 2S alloy; Alcoa No. 24 flux (automatic), Alcoa No. 27 flux (manual).
Tungsten-arc, argon atmosphere weld with 2S alloy; no flux.
Resistance welding. Spot, seam, and flash methods

½	110,000	7.0	1.0
1	140,000	7.0	1.0
1½	160,000	5.0	1.0
2	170,000	5.0	1.0

M *Composition Limits.* Bar and rod (Army Air Force Specification 11330), *components:* 3.5 to 6.0% Cu; 0.20 to 0.70% Bi; 0.20 to 0.70% Pb; *impurities:* 1.0% max Mn; 0.80% max Mg; 1.00% max Fe; 0.80% max Si; 0.25% max Cr; 0.30% max Zn; others (each) 0.05% max; others (total) 0.20% max.

2 *Consequences of exceeding impurity limits.* High iron reduces mechanical properties. High iron or magnesium impairs free-cutting characteristics. High silicon increases tool wear.

N 1 *Melting temperature.* 675 C to 745 C (1250 F to 1375 F)

3 *Alloying.* Add copper as pure metal or aluminum-rich alloy to base metal (pure), either in melt-down or molten alloy. Add bismuth as pure metal to molten base metal (pure). Add lead as pure metal to molten base metal (pure).

7 *Hot working temperature range.* 260 C to 480 C (500 to 900 F)

10 *Maximum reduction between anneals.* 50% or more depending on product

11 *Suited to forming by* machining or automatic screw-machining operations

15 *Heat treatment.*

Purpose	Temperature, deg Cent	Temperature, deg Fahr	Time, hours	Cooling
Complete annealing O	399 to 427	750 to 800	2	Furnace-cool to 500 F (50 °F per hr max)
Removal of cold work	343	650	No holding time required	Not critical
Solution heat treatment T4	499 to 527	930 to 980	10 min to 1 hr (salt bath) Longer time in air	Cold water quench Heavy or complicated forgings, water 150 to 212 F.
Precipitation T8 (Start with T4 material)	160 to 171	320 to 340	12 to 18	Not critical

17 *Joining. Resistance welding.* Flash methods

Al – 4 Cu – 0.6 Mn – 0.6 Mg – 0.5 Pb – 0.5 Bi

COMPILED BY L. E. HOUSEHOLDER*

A 2 *Trade name.* R 317

4 *Government number.* Army Air Force Spec. No. 11330-B (bar and rod); U. S. Army Ordnance No. AXS-1651 (bar and rod)

B 1 *Typical uses.* Forgings and free-machining stock for screw-machine products

C 1 *Density* at 20 C (68 F). 2.81 g per cu cm (0.101 lb per cu in.)

E 1 *Volume conductivity* referred to standard copper. 30%

11 *Electrolytic solution potential* of T temper versus saturated calomel electrode is minus 0.59 volt.

I 1 *General resistance to corrosion.* The corrosion resistance is best in the T temper. A rapid transfer from the furnace to the cold water quenching medium is necessary to obtain best resistance to corrosion.

K *Mechanical Properties. Quenched T*: tensile strength 61,000 psi; yield strength 35,000 psi; elongation 22% in 2 in.; Bhn 100; Rockwell B 73; modulus of elasticity 10,500,000 psi.

L 1 *Metallography.* Etching, grain size, Keller's etch; etching, microstructure, Keller's etch and other for aluminum alloy constituents. Lead and bismuth constituents easily seen in as-polished metallographic specimens.

3 *Corrosion test commonly used.* $NaCl + H_2O_2$; *see* Spec. AN-QQ-H-186a for detail.

* Chief Plant Metallurgist, Reynolds Metals Company, Grand Rapids, Mich.

M *Composition Limits* (Spec. AXS-1651 U. S. Army Ordnance). *Components*: 3.5 to 4.5% Cu; 0.4 to 1.0% Mn; 0.2 to 0.8% Mg; 0.3 to 0.7% Bi; 0.3 to 0.7% Pb; *impurities*: 1.0% max Fe; 1.0% max Si; 0.25% max Cr; 0.2% max Zn; other elements (each), 0.05% max; other elements (total), 0.20% max.

N 7 *Hot working temperature range.* 355 to 400 C (675 to 750 F)

9 *Annealing temperature.* 400 to 425 C (750 to 800 F), soak for one hour and cool at a rate not greater than 50 °F per hr to 500 F.

11 *Suited to forming* by forging or machining.

15 *Heat treatment.*

Purpose	Temperature, deg Cent	Temperature, deg Fahr	Time, hours	Atmosphere	Cooling
Solution heat treatment	499 to 510	930 to 950	Depends on thickness	Air or nitrate bath	Cold water quench
Aging (natural)	Room temperature		4 days minimum	.....	.....

17 *Joining.*
Rivet composition. 24 S-T4 or 17 S-T4.
Soldering, brazing and welding are not recommended.

condition O; 4.310 microhm, condition T6

11 Electrolytic solution potential versus N/10 calomel electrode is 0.68 volt, condition T4; 0.78 volt, condition T6 (53 g NaCl + 3 g H_2O_2 solution).

F *5 Emissivity* at 25 C (77 F). 0.035 to 0.07 in air

K *Mechanical Properties.*

Condition	Tensile Strength,(a) psi	Yield Strength,(b) psi	Elongation (c) percentage	Elongation (d) percentage	Bhn(e)	Shear Strength, psi
Bare Products						
O	27,000	14,000	..	18	45	18,000
T4	56,000	40,000	..	25	100	34,000
T6	70,000	60,000	..	13	135	42,000
Clad Sheet						
O	25,000	10,000	21	..	...	18,000
T4	59,000	38,000	18	..	...	39,000
T6	65,000	58,000	9	..	...	41,000

(a) In general, strengths and elongations are unchanged or improved at low temperatures.

(b) The compressive yield strength is approximately the same as the tensile yield strength. (c) Sheet specimens $\frac{1}{16}$ in. thick. (d) Round specimens ½ in. diam. (e) 500-kg load, 10-mm ball.

Endurance limit (bare products, conditions T4 and T6, 500,000,000 cycles) 18,000 psi, (condition O) 11,000 psi; modulus of elasticity (bare products) 10,600,000 psi, (clad sheet) 10,500,000 psi; modulus of rigidity 3,850,000 psi; torsional yield strength approximately 0.55 times the tensile yield strength; torsional ultimate strength approximately 0.65 times the tensile strength.

Strength and elongation at elevated temperatures after prolonged heating at testing temperatures:

Property	Temperature, deg Fahr: 75	300	400	500	600	700
Condition T6 (bare products)						
Tensile strength, psi	70,000	43,000	17,000	10,000	6000	4000
Yield strength, psi	60,000	39,000	13,000	8,000	4500	3500
Elongation, %	13	16	33	50	65	75

2 Directional properties (all tempers of sheet). Tensile strength and elongation are approximately equal in longitudinal and transverse directions. In forgings, transverse tensile strength approximately same as longitudinal. Transverse elongation approximately 70% of longitudinal.

L *2 Radiography.* Type A or 506 film with no intensifying screen, cardboard exposure holder, 36-in. focal distance, General Electric OX-250 unit, 2.1 H&D film density

Section, in.	Volts	Milliamperes	Time, min
½	75,000	9.0	1.0
1	105,000	7.0	1.0
1½	140,000	5.0	1.0
2	145,000	9.0	1.0

M *Composition Limits.* See Table I.

2 Consequences of exceeding impurity limits.
Core. High iron reduces tensile properties and formability. High chromium plus iron plus titanium may cause segregation.
Cladding. High copper lowers inherent resistance to corrosion of cladding and reduces potential difference between core and cladding.

N *1 Melting temperature.* 675 C to 745 C (1250 to 1375 F)

3 Alloying. Add copper as pure metal or aluminum-rich alloy to base metal (pure), either in melt-down or molten alloy. Add silicon as pure metal or aluminum-rich alloy to base metal (pure), either in melt-down or molten alloy. Add manganese as aluminum-rich alloy to melt-down or to molten base metal (pure). Add magnesium as pure metal to molten base metal.

7 Hot working temperature. 260 to 480 C (500 to 900 F)

10 Maximum reduction between anneals. 50% or more depending on product

15 Heat treatment.

Purpose	Temperature, deg Cent	Temperature, deg Fahr	Time, hours	Cooling
Complete annealing O	399 to 427	750 to 800	2	Furnace-cool to 500 F (50 °F per hr max)
Removal of cold work	343	650	No holding time required	Not critical
Solution heat treatment T4	496 to 513	925 to 950	10 min to 1 hr (salt bath)	Cold water quench
			Longer time in air	Heavy or complicated forgings, water 150 to 212 F
Precipitation T6 (Start with T4 material)	168 to 174	335 to 345	8 to 12	Not critical
	157 to 163	315 to 325	or 16 to 20	Not critical

17 Joining. Rivet compositions. Condition T6: A 17 S-T4, 17 S-T4, 24 S-T4, or steel. *Metal-arc weld* with 43 alloy; Alcoa No. 27 flux. *Carbon-arc weld* with 43 alloy; Alcoa No. 24 flux (automatic), Alcoa No. 27 flux (manual). *Tungsten-arc, argon atmosphere weld* with 43 alloy; no flux. *Resistance welding.* Spot, seam, and flash methods

Al – 4.5 Cu – 1.5 Mg – 0.6 Mn*

A *2 Trade name.* 24 S alloy
3 ASTM number. B 209-46T, Alloy CG21 and clad CG21 (sheet and plate, bare and clad); B 211-46T, Alloy CG21 (bar, rod and wire); B 210-46T, Alloy CG21 (tubing)
4 Government number. QQ-A-355 (sheet and plate, bare); QQ-A-362 (sheet and plate, clad); QQ-A-354 (bar, rod, shapes and wire); WW-T-785 (tubing)
6 Foreign equivalents. British BS 2L40 (bar, rod, shapes and wire); DTD 273 (tubing)
B *1 Typical uses.* Applications where higher strengths are desired than are provided by 17 S alloy. Aircraft structures, rivets, hardware and other miscellaneous structural applications are typical.
C *1 Density* at 20 C (68 F). 2.77 g per cu cm (0.100 lb per cu in.)
D *1 Liquidus temperature.* 638 C (1180 F)
2 Solidus temperature. 502 C (935 F)
6 Thermal expansion.

	Condition O	*Condition T4*
−60 to +20 C (−76 to +68 F).	.....	0.0000215 per °C
20 to 100 C (68 to 212 F).	0.0000228	0.0000232 per °C
20 to 200 C (68 to 392 F).	0.0000239	..... per °C
20 to 300 C (68 to 572 F).	0.0000247	..... per °C

11 Specific heat at 100 C (212 F). Approx 0.23 cal per g
16 Thermal conductivity at 25 C (77 F). 0.45 cgs, condition O; 0.29 cgs, condition T4
19 Recrystallization temperature. 345 C (650 F) approx, 50% reduction
E *1 Volume conductivity* referred to standard copper. 50%, condition O; 30%, condition T4
2 Electrical resistivity at 20 C (68 F). 3.448 microhm-cm, condition O; 5.747 microhm-cm, condition T4
11 Electrolytic solution potential versus N/10 calomel electrode is 0.68 volt, condition T4 (53 g NaCl + 3 ▮ H_2O_2 solution).
F *5 Emissivity* at 25 C (77 F). 0.035 to 0.07 in air
K *Mechanical Properties.*

Condition	Tensile Strength,(a) psi	Yield Strength,(b) psi	Elongation, (c) percentage	Elongation, (d) percentage	Bhn(e)	Shear Strength, psi
Bare Products						
O	27,000	11,000	19	22	42	18,000
T4	68,000	46,000	19	22	120	41,000
T36(f)	73,000	57,000	13	..	130	42,000
Clad Sheet						
T4	64,000	43,000	18	..	...	40,000
T36(f)	67,000	53,000	11	..	...	41,000
T81.....	66,000	60,000	7	..	...	.....
T86.....	70,000	66,000	6	..	...	.....

(a) In general, strengths and elongations are unchanged or improved at low temperatures.
(b) The compressive yield strength is approximately the same as the tensile yield strength.
(c) Sheet specimens $\frac{1}{16}$ in. thick
(d) Round specimens ½ in. diam
(e) 500-kg load, 10-mm ball
(f) Condition T36 is produced by a combination of heat treatment and cold work.

Modulus of elasticity for both bare and clad sheet is 10,600,000 psi, with two exceptions, namely: clad sheet (secondary) where the modulus value is more dependent on the thickness than on condition: 10,000,000 psi for sheet 0.064 in. and thicker, and 9,600,000 psi for sheet less than 0.064 in. thick. Secondary values for conditions T36, T81 and T86 are the same as for condition T4.
Endurance limit (bare products, condition T4, 500-000,000 cycles) 18,000 psi, (condition O) 12,000 psi; modulus of rigidity (bare products only) 3,850,000 psi; Poisson's ratio (all conditions, bare and clad products) 0.33; torsional yield strength approximately 0.55 times the tensile yield strength; torsional ultimate strength approximately 0.65 times the tensile strength.
Strength and elongation at elevated temperature after prolonged heating at testing temperature.

Property	Temperature, deg Fahr: 75	300	400	500	600	700
Condition T4 (bare products)						
Tensile strength, psi....	68,000	42,000	20,000	12,000	7000	5000
Yield strength, psi.....	46,000	37,000	16,000	10,000	5500	3500
Elongation, %	22	20	26	40	70	100

2 Directional properties (all tempers of sheet). Tensile strength and elongation are approximately equal in the longitudinal and transverse directions.
L *2 Radiography.* Same as for 17 S alloy (Al – 4 Cu – 0.5 Mg – 0.5 Mn)
M *Composition Limits.* See Table I.
2 Consequences of exceeding impurity limits.
Core. High iron reduces tensile properties and formability. High silicon reduces tensile properties. High chromium interferes with annealing. This effect is more noticeable when nickel is also present. Lead produces hot shortness. Cadmium produces hot shortness.
Cladding. High copper lowers inherent resistance to corrosion of cladding and reduces potential difference between core and cladding. The latter is particularly significant for artificially aged conditions.
N *1 Melting temperature range.* 675 C to 745 C (1250 to 1375 F)
3 Alloying. Add copper as pure metal or aluminum-rich alloy to base metal (pure), either in melt-down or molten alloy. Add magnesium as pure metal to molten base metal (pure).
7 Hot working temperature range. 260 C to 480 C (500 to 900 F)
10 Maximum reduction between anneals. 50% or more depending on product
15 Heat treatment.

Purpose	Temperature, deg Cent	Temperature, deg Fahr	Time, hours	Cooling
Complete annealing O	399 to 427	750 to 800	2	Furnace-cool to 500 F (50 °F per hr max)
Removal of cold work	343	650	No holding time required	Not critical
T4 Solution heat treatment	488 to 499	910 to 930	10 min to 1 hr (salt bath)	Cold water quench
T4 followed by Precipitation	Room		Longer time in air	
Precipitation T81	188 to 193	370 to 380	48 to 96 11 to 13	Not critical
	(Start with T4 material)			
Precipitation T84	188 to 193	370 to 380	8 to 10	Not critical
	(Start with T4 material stretched 3%)			
Precipitation T86	188 to 193	370 to 380	8 to 10	Not critical
	(Start with T36 material)			

17 Joining. Same as for 17 S alloy (Al – 4 Cu – 0.5 Mg – 0.5 Mn)

6 Foreign equivalents. British DTD 440 (tubing)
B *1 Typical uses.* Applications where good workability, very good resistance to corrosion, high fatigue strength and moderate static strength are desired. Aircraft fuel and oil lines, fuel tanks, miscellaneous marine and transportation applications are typical.
C *1 Density* at 20 C (68 F). 2.68 g per cu cm (0.097 lb per cu in.)
D *1 Liquidus temperature.* 649 C (1200 F)
2 Solidus temperature. 593 C (1100 F)
6 Thermal expansion (condition O).

−60 to +20 C	(−76 to +68 F).	0.0000220 per °C
20 to 100 C	(68 to 212 F).	0.0000238 per °C
20 to 200 C	(68 to 392 F).	0.0000249 per °C
20 to 300 C	(68 to 572 F).	0.0000258 per °C

11 Specific heat at 100 C (212 F). Approx 0.23 cal per g
16 Thermal conductivity at 25 C (77 F). 0.33 cal/sq cm/cm/°C/sec, condition O; 0.33 cal/sq cm/cm/°C/sec, condition H38
19 Recrystallization temperature. 290 C (550 F) approx, 50% reduction
E *1 Volume conductivity* referred to standard copper. 35%, condition O; 35%, condition H38
2 Electrical resistivity at 20 C (68 F). 4.926 microhm-cm, condition O; 4.926 microhm-cm, condition H38
11 Electrolytic solution potential versus N/10 calomel electrode is 0.85 volt (53 g NaCl + 3 g H_2O_2 solution).
F *5 Emissivity* at 25 C (77 F). 0.035 to 0.07 in air
K *Mechanical Properties.* See Table I.
Modulus of elasticity 10,200,000 psi; modulus of rigidity 3,850,000 psi; Poisson's ratio 0.33; torsional yield strength approximately 0.55 times the tensile yield strength; torsional ultimate strength approximately 0.65 times the tensile strength.
Strength and elongation at elevated temperatures after prolonged heating at the testing temperatures. See Table II.
2 Directional properties (various hard tempers of sheet). Tensile strength and elongation are slightly lower in transverse than in longitudinal direction.
L *2 Radiography.* Same as for 2 S alloy (commercially pure aluminum)
M *Composition Limits.* See Table III.
2 Consequences of exceeding impurity limits. High copper lowers resistance to corrosion. High iron plus silicon reduces formability. High silicon may reduce tensile properties.

Table I. Mechanical Properties of Al – 2.5 Mg – 0.25 Cr

Condition	Tensile Strength, (a) psi	Yield Strength, (b) psi	Elongation, (c) (d) %	Bhn (e)	Shear Strength, psi	Endurance Limit, (f) psi
Annealed O	29,000	14,000	25 30	45	18,000	17,000
H32	34,000	26,000	12 18	62	20,000	17,500
H34	37,000	29,000	10 14	67	21,000	18,000
H36	39,000	34,000	8 10	74	23,000	18,500
H38	41,000	36,000	7 8	85	24,000	19,000

(a) In general, strength and elongation are unchanged or improved at low temperatures.
(b) The compressive yield strength is approximately the same as the tensile yield strength.
(c) Sheet specimens $\frac{1}{16}$ in. thick
(d) Round specimens ½ in. in diam
(e) 500-kg load, 10-mm ball
(f) Based on 500,000,000 cycles using R. R. Moore type rotating-beam machine.

N *1 Melting temperature range.* 675 to 745 C (1250 to 1375 F).
3 Alloying. Add magnesium as pure metal to molten base metal (pure). Add chromium as pure aluminum-rich alloy to melt-down or molten base metal (pure).
7 Hot working temperature range. 260 to 510 C (500 to 950 F).
10 Maximum reduction between anneals. 50% or more depending on product
15 Heat Treatment. Annealing at 345 C (650 F); holding at temperature not required.

Table II. Strength and Elongation of Al – 2.5 Mg – 0.25 Cr

Property	Temperature, deg Fahr 75	300	400	500	600	700
Annealed O						
Tensile strength, psi....	29,000	23,000	18,000	12,000	7500	5000

11 *Specific heat* at 100 C (212 F). Approx 0.23 cal per g
16 *Thermal conductivity* at 25 C (77 F). 0.28 cgs, condition O; 0.26 cgs, condition H38
E 1 *Volume conductivity* referred to standard copper. 29%, condition O; 27%, condition H38
2 *Electrical resistivity* at 20 C (68 F). 5.945 microhm-cm, condition O; 6.386 microhm-cm, condition H38

*Compiled by Aluminum Company of America

11 *Electrolytic solution potential* versus N/10 calomel electrode is 0.87 volts (53 g NaCl + 3 ■ H_2O_2 solution).
F 5 *Emissivity* at 25 C (77 F). 0.035 to 0.07 in air
K *Mechanical Properties.*

Condition	Tensile Strength, (a) psi	Yield Strength, (b) psi	Elongation, (c) percentage	Endurance Limit, (d) psi
O	42,000	20,000	35	20,000
H38	58,000	48,000	7	22,000

(a) In general, strengths and elongation are unchanged or improved at low temperatures.
(b) The compressive yield strength is approximately the same as the tensile yield strength.
(c) Round specimens ½ in. diam
(d) Based on 500,000,000 cycles using R. R. Moore type rotating-beam machine

Modulus of elasticity 10,300,000 psi; modulus of rigidity 3,850,000 psi; Poisson's ratio 0.33; torsional yield strength approximately 0.55 times the tensile yield strength; torsional ultimate strength approximately 0.65 times the tensile strength.
L 2 *Radiography.* Type A or 506 film with no intensifying screen, cardboard exposure holder, 36-in. focal distance. General Electric OX-10 unit, 2.1 H&D film density. For data, see Table I on the next page.

Table I. Radiography of Al – 5.2 Mg – 0.1 Mn – 0.1 Cr

Section, in.	Volts	Milliamperes	Time, min
½	60,000	10.0	1.0
1	90,000	6.7	1.0
1½	120,000	5.0	1.0
2	140,000	5.0	1.0

M *Composition Limits.* Wire (AN-QQ-W-298), *components:* 4.5 to 5.6% Mg; 0.05 to 0.20% Mn; 0.05 to 0.20% Cr; *impurities:* 0.10% max Cu; 0.30% max Si; 0.30% max Fe; others (each) 0.05% max; others (total) 0.15% max.

2 Consequences of exceeding impurity limits. High copper lowers resistance to corrosion. High silicon may reduce tensile properties.

N *1 Melting temperature.* 675 to 745 C (1250 to 1375 F)

3 Alloying. Add magnesium as pure metal to molten base metal (pure). Add manganese as aluminum-rich alloy to melt-down or molten base metal (pure). Add chromium as aluminum-rich alloy to melt-down or molten base metal (pure).

7 Hot working temperature. 260 to 510 C (500 to 950 F)

10 Maximum reduction between anneals 50% or more depending on product

15 Heat treatment. Annealing at 345 C (650 F); holding at temperature not required.

17 Joining.
Rivet compositions. 56 S (if any applications)
Metal-arc weld with 56 S alloy; Alcoa No. 27 flux.
Carbon-arc weld with 56 S alloy; Alcoa No. 24 flux (automatic), Alcoa No. 27 flux (manual).
Tungsten-arc, argon atmosphere weld with 56 S alloy; no flux.
Resistance welding. Spot, seam, and flash methods

Al – 1.0 Mg – 0.6 Si – 0.25 Cu – 0.25 Cr*

A *2 Trade name.* 61 S alloy

3 ASTM number. B 209-46T, Alloy GS21 (sheet and plate); B 211-46T, Alloy GS21 (bar, rod and wire); B 210-46T, Alloy GS21 (tubing)

4 Government number. QQ-A-327 (sheet and plate); QQ-A-325 (bar, rod, shapes, and wire); WW-T-789 (tubing)

B *1 Typical uses.* Applications where good strength, workability and very good resistance to corrosion are required. Aircraft landing mats, pontoon boats, canoes, furniture, vacuum cleaner tubing and transportation equipment are typical.

C *1 Density* at 20 C (68 F). 2.70 g per cu cm (0.098 lb per cu in.)

D *1 Liquidus temperature.* 652 C (1205 F)

2 Solidus temperature. 582 C (1080 F)

6 Thermal expansion.

O	40,000	20,000	..	■	...	10,400,000	.....
T6	88,000	80,000	..	10	150	10,400,000	47,000
Other Bare Products							
O	33,000	15,000	17	12	...	.....	.....
T6	82,000	72,000	11	10	150	.....	.....
Clad Sheet							
O	32,000	14,000	16	..	...	10,400,000 (primary) 9,600,000 (secondary)	.....
T6	76,000	66,000	11	..	...	10,400,000 (primary) 9,600,000 (secondary)	46,000

(a) In general, strengths and elongation are unchanged or improved at low temperatures.
(b) The compressive yield strength is approximately the same as the tensile yield strength
(c) Sheet specimens $\frac{1}{16}$ in. thick
(d) Round specimens ½ in. in diam
(e) 500-kg load, 10-mm ball

Endurance limit (500,000,000 cycles) extrusions, condition T6, 22,500 psi; modulus of rigidity 3,850,000 psi; Poisson's ratio 0.33; torsional yield strength approximately 0.55 times the tensile yield strength; torsional ultimate strength approximately 0.65 times the tensile strength.

Strength and elongation at elevated temperatures after prolonged heating at the testing temperatures.

Property	Temperature, deg Fahr: 75	300	400	500	600	700
Condition T6 (extrusions)						
Tensile strength, psi	88,000	25,000	15,000	12,000	8500	6500
Yield strength, psi	80,000	22,000	12,000	8,000	6000	5000
Elongation, %	10	32	55	60	68	75

2 *Directional properties* (all tempers of sheet). Tensile strength and elongation are approximately equal in the longitudinal and transverse directions.

L 2 *Radiography.* Same as for 14S alloy (Al–4.4 Cu–0.8 Si–0.8 Mn–0.4 Mg)

M *Composition Limits.* See Table I (next page).

2 *Consequences of exceeding impurity limits.*
Core. High iron increases segregation difficulties, adversely affects formability and may reduce resistance to corrosion. High silicon will reduce mechanical properties. Nickel reduces resistance to corrosion. Lead produces hot shortness.
Cladding. High copper lowers potential difference between cladding and core.

N 1 *Melting temperature.* 675 to 745 C (1250 to 1375 F)

3 *Alloying.* Add zinc as pure metal to molten base metal (pure). Add magnesium as pure metal to molten base metal (pure). Add copper as pure metal or aluminum-rich alloy to base metal (pure), either in melt-down or molten alloy. Add manganese as aluminum-rich alloy to melt-down or molten base metal (pure). Add chromium as aluminum-rich alloy to melt-down or molten base metal (pure).

7 *Hot working temperature.* 260 to 455 C (500 to 850 F)

10 *Maximum reduction between anneals.* 40% or more depending on product.

15 *Heat treatment.*

Purpose	Temperature, deg Cent	Temperature, deg Fahr	Time, hours	Cooling
Complete annealing O	413 to 454	775 to 850	2	Air cool
followed by	232	450	4	Not critical
Removal of cold work	413	775	No holding time required	Not critical
Solution heat treatment W.	460 to 499	860 to 930(a)	10 min to 1 hr (salt bath) Longer time in air	Cold water quench
Precipitation T6 (Start with W material)	118 to 124	245 to 255	22 to 26	Not critical
or heat to	96 to 102	205 to 215	4 to 6 (b)	
and then cool to room temp and reheat to	154 to 160	310 to 320	8 to 10	Not critical

(a) Extrusions must be heated between 860 and 880 F
(b) U. S. Patent 1,858,092

17 *Joining.* Same as for 17S (Al–4 Cu–0.5 Mg–0.5 Mn)

* Compiled by Aluminum Company of America

Table I. Composition Limits of Al – 5.5 Zn – 2.5 Mg – 1.5 Cu – 0.3 Cr – 0.2 Mn

Al – 6.4 Zn – 2.5 Mg – 1.2 Cu

COMPILED BY L. E. HOUSEHOLDER*

A *2 Trade name.* R 303

B *1 Typical uses.* Aircraft and other transportation

2 Precautions in use. To ensure meeting the specified mechanical properties and to obtain maximum resistance to stress-corrosion cracking, the prescribed heat treating practices should be followed carefully.

C *1 Density* at 20 C (68 F). 2.82 g per cu cm (0.102 lb per cu in.)

E *11 Electrolytic solution potential* of T temper versus saturated calomel electrode is minus 0.77 volt.

I *1 General resistance to corrosion.* The corrosion resistance is best if the heat treating practices are followed carefully. The T315 temper is somewhat more resistant than other tempers to both general corrosion and stress-corrosion cracking. For maximum resistance to corrosion the clad sheet is recommended.

K *Mechanical Properties.*

Condition	Section, in.	Tensile Strength, psi	Yield Strength, psi	Elongation in 2 in., percentage	Rockwell Hardness
Annealed	0.064 sheet	30,000	15,000	18	E 57 to 62
Quenched T275 and aged T315	0.064 sheet	79,000	73,000	9	B 89 to 93
		75,000	69,000	9	B 87 to 91
Quenched T275 and aged T315	extrusions	85,000	80,000	9	.....
	extrusions	79,000	73,000	9	.....

Shear strength (T275) 48,000 psi, (T315) 47,000 psi
Other mechanical properties (same for both T275 and T315)
Modulus of elasticity. 10,400,000 psi.
Endurance limit (500,000,000 cycles). 23,000 psi
Shear modulus. 3,900,000 psi
Compressive yield strength. Same as tensile yield strength
Bearing yield strength. Edge distance 1.50*D*, 1.4 times tensile yield. Edge distance 2.00*D*, 1.6 times tensile yield
Bearing ultimate strength. Edge distance 1.50*D*, 1.5 times tensile strength
Edge distance 2.00*D*, 1.9 times tensile strength

L *1 Metallography.* Etching, grain size (T condition) HNO_3-CH_3COOH (*see reference*); etching, microstructure (*see reference*).

3 Corrosion test commonly used. NaCl + H_2O_2, *see* Spec. AN-QQ-H-186a for detail.

N *7 Hot working temperature range.* 370 to 425 C (700 to 800 F)

9 Annealing temperature. 355 to 370 C (675 to 700 F), cool to 450 F and soak for 4 hr.

11 Suited to forming by drawing, drop-hammer forging, stretcher forming, coining or machining. Very little forming can be done in the T condition, but the alloy has good formability in the annealed temper or in the freshly quenched condition.

12 Precautions in forming. When forming in the freshly quenched condition, the forming should be done within one hour after quenching, or the alloy should be stored in dry ice until ready.

15 Heat treatment.

Purpose	Temperature, deg Cent	Temperature, deg Fahr	Time, hours	Atmosphere	Cooling
Solution heat treatment	432 to 449	810 to 840	Depends on thickness	Air or nitrate bath	Cold water
Age harden T275	132 to 138	270 to 280	24	Air	Air
Age harden T315	154 to 160	310 to 320	8	Air	Air
Incubation period	Room temperature		24		

17 Joining. Rivet compositions. 24 S-T4 or 17 S-T4. *Soldering, brazing, gas welding and carbon-arc welding* are not recommended. *Spot welding* of bare sheet is not recommended. Clad sheet can be spot welded satisfactorily.

* Chief Plant Metallurgist, Reynolds Metals Company, Grand Rapids, Mich.

CASTING ALLOYS

Al – 12 Si*

A *2 Trade name.* 13 alloy (die casting)
3 ASTM number. B 85–46T, Alloy S5
4 Government number. QQ–A–591, Class 1 (die casting)

B *1 Typical uses.* Applications where excellent castability and resistance to corrosion are required. Miscellaneous thin-walled and intricately designed castings are typical.

C *1 Density* at 20 C (68 F). 2.66 g per cu cm (0.096 lb per cu in.)

D *1 Liquidus temperature.* 585 C (1085 F)
2 Solidus temperature. 574 C (1065 F)
6 Thermal expansion

20 to 100 C (68 to 212 F). 0.0000200 per °C
20 to 200 C (68 to 392 F). 0.0000205 per °C
20 to 300 C (68 to 572 F). 0.0000215 per °C

11 Specific heat at 100 C (212 F). Approx 0.23 cal per g
13 Latent heat of fusion. Approx 93 cal per g
16 Thermal conductivity at 25 C (77 F). 0.37 cal/sq cm/cm/°C/sec

E *1 Volume conductivity* referred to standard copper. 39%
2 Electrical resistivity at 20 C (68 F). 4.421 microhm-cm

F *5 Emissivity.* 0.035 to 0.07 at 25 C (77 F) in air

K *Mechanical Properties. Die cast:* Tensile strength 37,000 psi; yield strength 18,000 psi; elongation (round specimens, ¼-in. diam) 1.8%; modulus of elasticity 10,300,000 psi; endurance limit (based on 500,000,000 cycles using R. R. Moore type of rotating-beam machine) 15,000 psi; modulus of rigidity 3,850,000 psi; Poisson's ratio 0.33.

L *2 Radiography.* Type A or 506 film using no intensifying screen, cardboard exposure holder, 36-in. focal distance, General Electric OX–10 unit, 2.1 H&D film density.

* Compiled by Aluminum Company of America

Section, in.	Volts	Milliamperes	Time, min
½	60,000	10.0	1.0
1	90,000	6.7	1.0
1½	120,000	5.0	1.0
2	140,000	5.0	1.0

M *Composition Limits. Die cast* (QQ–A–591, Class 1), *components:* 11.0 to 13.0% Si; *impurities:* 2.0% max Fe; 0.60% max Cu; 0.10% max Mg; 0.30% max Mn; 0.50% max Zn; 0.50% max Ni; 0.10% max Sn; others (total) 0.20% max.

2 *Consequences of exceeding impurity limits.* Relatively large quantities of impurities may be present before serious effects are detected. In general, increasing copper will lower resistance to corrosion and increasing iron and magnesium will lower ductility.

N 1 *Melting temperature range.* 649 to 760 C (1200 to 1400 F)

2 *Die-casting temperature range.* 635 to 704 C (1175 to 1300 F)

3 *Alloying.* Add silicon as pure metal or aluminum-rich alloy to base metal (pure), either in melt-down or molten alloy.

5 *Type of flux* for remelting for casting. Gaseous type, nitrogen or chlorine; or solid, aluminum chloride base

17 *Joining.*
Rivet compositions. 53 S-T4, 53 S-T6, 53 S-T61
Soft solder after copper plating, then use methods applicable to copper-base alloys.
Resistance welding. Flash method

Al – 5 Si*

A 2 *Trade name.* 43 alloy (sand casting, permanent mold casting and die casting)

3 *ASTM number.* B 85-46T, Alloy S4 (die casting); B 26-46T, Alloy S1 and S2 (sand); B 108–46T, Alloy S1 and S2 (permanent mold)

4 *Government number.* QQ-A-591, Class 3 (die casting); QQ–A-601, Class 2 (sand); QQ–A-596, Class 7 (permanent mold)

B 1 *Typical uses. Die casting:* applications where above-average ductility and excellent resistance to corrosion are required.
Sand and permanent mold casting: applications where very good castability and resistance to corrosion with moderate strength are required. Cooking utensils, food-handling equipment, marine fittings and miscellaneous thin-section castings are typical.

C 1 *Density* at 20 C (68 F). 2.69 g per cu cm (0.097 lb per cu in.)

D 1 *Liquidus temperature.* 629 C (1165 F)

2 *Solidus temperature.* 577 C (1070 F)

6 *Thermal expansion*

20 to 100 C (68 to 212 F). 0.0000220 per °C
20 to 200 C (68 to 392 F). 0.0000230 per °C
20 to 300 C (68 to 572 F). 0.0000240 per °C

11 *Specific heat* at 100 C (212 F). Approx 0.23 cal per g

13 *Latent heat of fusion.* Approx 93 cal per g

16 *Thermal conductivity* at 25 C (77 F). 0.35 cal/sq cm/cm/°C/sec, as cast; 0.39 cal/sq cm/cm/°C/sec, annealed*

E 1 *Volume conductivity* referred to standard copper.
37%, as cast (sand, permanent mold and die castings)
42%, annealed (sand and permanent mold)*

2 *Electrical resistivity* at 20 C (68 F)
4.660 microhm-cm, as cast (sand, permanent mold and die castings)
4.105 microhm-cm, annealed (sand and permanent mold)*

11 *Electrolytic solution potential* versus N/10 calomel electrode is 0.83 volt, sand cast; 0.82 volt, permanent mold cast (53 g NaCl + 3 g H_2O_2 solution)

F 5 *Emissivity.* 0.035 to 0.07 at 25 C (77 F) in air

K *Mechanical Properties.* See Table I.
Modulus of elasticity 10,300,000 psi; modulus of rigidity 3,850,000 psi; Poisson's ratio 0.33.

L 2 *Radiography.* Same as for 13 alloy (Al – 12 Si)

M *Composition Limits.* See Table II.

2 *Consequences of exceeding impurity limits.* For die-cast alloy, relatively large quantities of impurities may be present before serious effects are detected. In general, increasing copper will tend to lower resistance to corrosion and increasing iron and magnesium will tend to lower ductility.
For the sand and permanent mold cast alloys, high copper, iron, or nickel decrease ductility and resistance to corrosion. Increasing magnesium reduces ductility.

N 1 *Melting temperature range.*
649 to 760 C (1200 to 1400 F) (die casting)
677 to 816 C (1250 to 1500 F) (sand and permanent mold casting)

2 *Casting temperature range.*
635 to 704 C (1175 to 1300 F) (die casting)
677 to 788 C (1250 to 1450 F) (sand and permanent mold casting)

3 *Alloying.* Add silicon as pure metal or aluminum-rich alloy to molten base metal (pure), either in melt-down or molten alloy.

5 *Type of flux* for remelting for casting. Gaseous type,

* Compiled by Aluminum Company of America
* Sand and permanent mold castings are not usually annealed

Table I. Mechanical Properties of Al – 5 Si

Form	Tensile Strength,[a] psi	Yield Strength, psi	Elongation,[b] percentage	Elongation,[c] percentage	Brinell Hardness Number[d]	Shear Strength, psi	Endurance Limit,[e] psi	Compressive Yield Strength, psi
Die cast	30,000	14,000	7.0	..	..	.....	....	.....
Sand cast	19,000	9,000	..	6.0	40	14,000	6,500	10,000
Permanent mold cast	24,000	9,000	..	9.0	45	18,000	....	9,000

(a) In general, strengths and elongations remain unchanged or improve at low temperatures.
(b) Round specimens, ¼-in. diam
(c) Round specimens, ½-in. diam
(d) 500-kg, 10-mm ball
(e) Based on 500,000,000 cycles using R. R. Moore type of rotating-beam machine.

Table II. Composition Limits of Al – 5 Si

Form	Designation	Components: Si min	Components: Si max	Impurities: Fe max	Cu max	Mg max	Mn max	Zn max	Ti max	Others total max
Die cast	QQ-A-591, Class 3	4.5	6.0	2.00	0.60	0.10	0.30	0.50	...	0.20

nitrogen or chlorine; or solid type, aluminum chloride base.

17 *Joining.*
Rivet compositions. 53 S-T4, 53 S-T6, 53 S-T61
Soft solder with copper plate and use methods applicable to copper-base alloys, for die-cast alloy. Use Alcoa No. 802, no flux, or rub-tin with Alcoa No. 802 for sand and permanent mold castings.
The following details apply only to the sand and permanent mold casting alloys, unless otherwise noted.
Braze with Alcoa No. 717; Alcoa No. 33 flux; flame either reducing oxyacetylene or reducing oxyhydrogen.
Atomic-hydrogen weld with 43 alloy; Alcoa No. 22 flux.
Oxyacetylene weld with 43 alloy; Alcoa No. 22 flux; neutral flame.
Metal-arc weld with 43 alloy; Alcoa No. 27 flux.
Carbon-arc weld with 43 alloy; Alcoa No. 24 flux (automatic), Alcoa No. 27 (manual).
Tungsten-arc, argon atmosphere weld with 43 alloy; no flux.
Resistance weld. Flash method for die-cast alloys. Spot, seam and flash methods for sand and permanent mold cast alloys.

Al – 5 Si – 4 Cu*

A 2 *Trade name.* 85 alloy (die casting)
3 *ASTM number.* B 85-46T, Alloy SC2

COMPILED BY O. TICHY*

A 2 *Trade name.* Allcast (sand and permanent mold casting)
3 *ASTM number.* B 26-46T; B 108-46T, Alloy SC8
B 1 *Typical uses.* A general-purpose aluminum alloy for sand and permanent mold castings, which can be used without heat treatment to develop better mechanical properties than common aluminum alloys that are not heat treated; or can be solution heat treated to provide mechanical properties required by most current specifications for heat treatable aluminum alloys.
2 *Precautions in use.* Because this alloy contains 5.5% Si, it is subject to about 0.001 in. per in. growth if heated to approximately 400 F in use or fabrication. A heat treatment of 5 hr at 450 F applied to rough castings will prevent further dimensional change.
C 1 *Density* at 20 C (68 F). 2.76 g per cu cm (0.100 lb per cu in.)
D 6 *Thermal expansion* 20 to 100 C (68 to 212 F). 0.0000219 per °C
16 *Thermal conductivity* at 20 C (68 F). 0.25 cal/sq cm/cm/°C/sec, as cast; 0.28, stress relieved; 0.27, solution heat treated and aged; 0.33, solution heat treated and stress relieved
E 1 *Volume conductivity* referred to standard copper.
27%, as cast
30%, stress relieved
30%, solution heat treated and aged
36%, solution heat treated and stress relieved
K *Mechanical Properties.* See Table I.
M *Composition Limits. Sand and permanent mold cast, components:* 2.5 to 3.5% Cu; 4.5 to 6.0% Si; *impurities:* 0.2% max Ti; 1.2% max Fe; 0.15% max Mg; 0.8% max Mn; 0.5% max Ni; 1.0% max Zn; others (total) 1.0% max.
N 6 *Precautions in melting.* If the metal is heated to more than 1375 F some pinhole porosity may result. For the production of castings free from pinhole porosity, made with pouring temperatures of over 1375 F, the melt should be degassed with chlorine, nitrogen, or boron trichloride.

* Research Laboratory, National Smelting Company, Cleveland

Table I. Mechanical Properties of Al – 5 Si – 3 Cu

Condition	Tensile Strength, psi	Yield Strength,(a) psi	Elongation,(b) percentage	Rockwell E Hardness	Endurance Limit,(c) psi	Compressive Yield Strength, psi	Charpy Impact Value, ft-lb
Sand Cast							
As cast	27,000	14,000	2.5	E 65	....	....	1.0
Stress relieved	29,000	18,000	2.0	E 67	....	19,000	0.8
Solution heat treated and aged	35,000	20,000	4.0	E 80	10,500	25,000	1.6
Solution heat treated and stress relieved	37,000	23,000	2.5	E 81	....	30,000	1.0
Permanent Mold Cast

Stress relieved	37,000	22,000	2.0	E 82	....	24,000	0.8
Solution heat treated and aged	42,000	22,000	5.0	E 85	....	24,000	2.0
Solution heat treated and stress relieved	42,000	23,000	3.0	E 86	....	24,000	1.0

(a) 0.2% offset
(b) Round specimens, ½-in. diam
(c) Based on 500,000,000 cycles using R. R. Moore type of rotating-beam machine.

Al – 5.5 Si – 4.5 Cu*

A 2 *Trade name.* A 108 alloy (permanent mold casting)
3 *ASTM number.* B 108-46T, Alloy SC1
4 *Government number.* QQ-A-596, Class 5
B 1 *Typical uses.* Applications where good casting characteristics, good weldability, pressure tightness, and moderate strength are required. Ornamental grilles, reflectors, general-purpose castings are typical.
C 1 *Density* at 20 C (68 F). 2.79 g per cu cm (0.101 lb per cu in.)
D 1 *Liquidus temperature.* 616 C (1140 F)
2 *Solidus temperature.* 516 C (960 F)
6 *Thermal expansion*
20 to 100 C (68 to 212 F). 0.0000215 per °C
20 to 200 C (68 to 392 F). 0.0000225 per °C
20 to 300 C (68 to 572 F). 0.0000230 per °C
11 *Specific heat* at 100 C (212 F). Approx 0.23 cal per g
13 *Latent heat of fusion.* Approx 93 cal per g
16 *Thermal conductivity* at 25 C (77 F). 0.34 cal/sq cm/cm/°C/sec
E 1 *Volume conductivity* referred to standard copper. 37%
2 *Electrical resistivity* at 20 C (68 F). 4.660 microhm-cm
11 *Electrolytic solution potential* versus N/10 calomel electrode is 0.75 volts (53 g NaCl + 3 g H_2O_2 solution).
F 5 *Emissivity.* 0.035 to 0.07 at 25 C (77 F) in air
K *Mechanical Properties. Permanent mold cast:* Tensile strength 28,000 psi; yield strength 16,000 psi; compressive yield strength 16,000 psi; elongation (round specimen, ½-in. diam) 2.0%; Bhn (500-kg load, 10-mm ball) 70; modulus of elasticity 10,300,000 psi; shear strength 25,000 psi; modulus of rigidity 3,850,000 psi; Poisson's ratio 0.33.
L 2 *Radiography.* Same as for 85 alloy (Al – 5 Cu – 4 Si)
M *Composition Limits. Permanent mold cast* (QQ-A-596, Class 5), *components*: 5.0 to 6.0% Si; 4.0 to 5.0% Cu; *impurities*: 1.00% max Fe; 0.30% max Mn; 0.10% max Mg; 0.50% max Zn; 0.20% max Ti; others (total) 0.50% max.
2 *Consequences of exceeding impurity limits.* High iron, zinc, or tin decreases mechanical properties. Magnesium decreases ductility.

17 Joining. Rivet compositions. 53 S-T4, 53 S-T6, 53 S-T61. Other joining methods same as for 122 alloy (Al – 10 Cu – 0.2 Mg)

* Compiled by Aluminum Company of America

Al–12 Si–1.5 Cu–0.7 Mn–0.7 Mg

COMPILED BY F. ROMANO*

A *2 Trade name.* Red X-13 (permanent mold casting)
3 ASTM number. B 108-46T, Alloy SC41
4 Government number. QQ-A-596; 46 A 15 (Interim)

B *1 Typical uses.* An aluminum alloy for pistons in internal combustion engines, which combines high strength at elevated temperatures with a low coefficient of expansion.

* Research Laboratory, National Smelting Company, Cleveland

2 Precautions in use: For use in pistons this alloy must be given a degrowthing heat treatment for about 8 hours at 400 F.

C *1 Density* at 20 C (68 F). 2.7 ■ per cu cm (0.098 lb per cu in.)

D *6 Thermal expansion*
20 to 100 C (68 to 212 F). 0.0000201 per °C
20 to 200 C (68 to 392 F). 0.0000208 per °C

20 to 300 C (68 to 572 F). 0.0000217 per °C
20 to 400 C (68 to 752 F). 0.0000223 per °C

K *Mechanical Properties.* See table at right.

M *Composition Limits. Permanent mold cast, components*: 1.0 to 2.0% Cu; 0.4 to 1.0% Mg; 0.5 to 0.9% Mn; 11.0 to 13.0% Si; *impurities:* 0.2% max Ti; 0.9% max Fe; 0.05% max Ni; 0.4% max Zn; others (total) 0.5% max.

N 5 *Type of flux.* None required.

6 *Precautions in melting.* Loss of magnesium should be controlled.

Condition	Tensile Strength, psi	Yield Strength,[a] psi	Elongation,[b] percentage	Rockwell E Hardness	Brinell Hardness Number[c]
		Permanent Mold Cast			
Stress relieved	36,000	....	0.5	E 92	100
400 F for 8 hr	40,000	....	..	E 97	115
Solution heat treated and aged	43,000	38,000	1.0	E 92	100

(a) 0.2% offset (b) Round specimen, ½-in. diam (c) 500-kg load, 10-mm ball

Al – 4 Cu – 2 Ni – 1.5 Mg*

A 2 *Trade name.* 142 alloy (sand and permnanent mold casting)

3 *ASTM number.* B 26-46T, Alloy CN21 (sand); B 108-46T, Alloy CN21 (permanent mold)

4 *Government number.* QQ-A-601, Class 6 (sand); QQ-A-596, Class 3 (permanent mold)

B 1 *Typical uses.* Applications where excellent high-temperature strength is required. Motorcycle, diesel and aircraft pistons, air-cooled cylinder heads, aircraft generator housings are typical.

C 1 *Density* at 20 C (68 F). 2.81 g per cu cm (0.101 lb per cu in.)

D 1 *Liquidus temperature.* 629 C (1165 F)

2 *Solidus temperature.* 535 C (995 F)

6 *Thermal expansion*

20 to 100 C (68 to 212 F). 0.0000225 per °C
20 to 200 C (68 to 392 F). 0.0000235 per °C
20 to 300 C (68 to 572 F). 0.0000245 per °C

11 *Specific heat* at 100 C (212 F). Approx 0.23 cal per g

13 *Latent heat of fusion.* Approx 93 cal per g

16 *Thermal conductivity* at 25 C (77 F).

0.40 cal/sq cm/cm/°C/sec, sand, condition T21
0.32 cal/sq cm/cm/°C/sec, sand, condition T571
0.36 cal/sq cm/cm/°C/sec, sand, condition T77
0.31 cal/sq cm/cm/°C/sec, permanent mold, condition T61

E 1 *Volume conductivity* referred to standard copper.
44%, sand, condition T21
34%, sand, condition T571
37%, sand, condition T77
32%, permanent mold, condition T61

2 *Electrical resistivity* at 20 C (68 F).
3.918 microhm-cm, sand, condition T21
5.071 microhm-cm, sand, condition T571
4.660 microhm-cm, sand, condition T77
5.388 microhm-cm, permanent mold, condition T61

F 5 *Emissivity.* 0.035 to 0.07 at 25 C (77 F) in air

K *Mechanical Properties.* See Tables I and II. Modulus of elasticity 10,300,000 psi; modulus of rigidity 3,850,000 psi; Poisson's ratio 0.33.

L 2 *Radiography.* Same as for 85 alloy (Al – 5 Cu – 4 Si)

M *Composition Limits.* See Table III.

2 *Consequences of exceeding impurity limits.* High iron may cause shrinkage difficulties. High silicon de-

Table I. Mechanical Properties of Al – 4 Cu – 2 Ni – 1.5 Mg

Condition	Tensile Strength,[a] psi	Yield Strength, psi	Elongation,[b] percentage	Brinell Hardness Number[c]	Shear Strength, psi	Endurance Limit,[d] psi	Compressive Yield Strength, psi
			Sand Cast				
T21	27,000	18,000	1.0	70	21,000	6,500	18,000
T571	32,000	28,000	0.5	85	27,000	8,000	34,000
T77	28,000	25,000	2.0	75	24,000	9,500	.....
			Permanent Mold Cast				
T571	40,000	34,000	1.0	105	26,000	10,500	34,000
T61	47,000	42,000	0.5	110	31,000	9,500	46,000

(a) In general, strengths and elongations remain unchanged or improve at low temperatures.
(b) Round specimens, ½-in. diam
(c) 500-kg load, 10-mm ball
(d) Based on 500,000,000 cycles using R. R. Moore type of rotating-beam machine.

Table II. Strength and Elongation of Al – 4 Cu – 2 Ni – 1.5 Mg at Elevated Temperatures
After prolonged heating at testing temperatures

Property	Temperature, deg Fahr 75 F	300 F	400 F	500 F	600 F
		Sand Cast, Condition T21			
Tensile strength, psi	27,000	27,000	21,000	16,000	8,000
Yield strength, psi	18,000	18,000	14,000	8,000	4,000
Elongation, %	1.0	1.0	1.5	3.0	9.0
		Permanent Mold Cast, Condition T571			
Tensile strength, psi	40,000	37,000	28,000	15,000	9,000
Yield strength, psi	34,000	33,000	22,000	9,000	5,000
Elongation, %	1.0	1.0	2.0	10.0	30.0

Table III. Composition Limits of Al – 4 Cu – 2 Ni – 1.5 Mg

Form	Designation	Components Cu min	Cu max	Mg min	Mg max	Ni min	Ni max	Impurities Fe max	Si max	Mn max	Zn max	Ti max	Others total max
Sand cast	QQ-A-601, Class 6	3.5	4.5	1.2	1.8	1.7	2.3	1.00	0.80	0.10	0.03	0.20	0.30
Permanent mold cast	QQ-A-596, Class 3	3.5	4.5	1.2	1.8	1.7	2.3	1.00	0.70	0.30	0.10	0.20	0.30

creases mechanical properties. Chromium decreases thermal conductivity.

N 1 *Melting temperature.* 677 to 816 C (1250 to 1500 F)
2 *Casting temperature range.* (sand) 677 to 788 C (1250 to 1450 F), (permanent mold) 677 to 788 C (1250 to 1450 F)
3 *Alloying.* Add copper as pure metal or aluminum-rich alloy to base metal (pure), either in melt-down or molten alloy. Add magnesium as pure metal to molten base metal (pure). Add nickel as aluminum-rich alloy to melt-down or molten base metal (pure).
5 *Type of flux* for remelting for casting. Gaseous type, nitrogen or chlorine; or solid type, aluminum chloride base.
15 *Heat treatment.* See right-hand column.
17 *Joining.* Same as for 122 alloy (Al – 10 Cu – 0.2 Mg)

Purpose	Temperature, deg Cent	Temperature, deg Fahr	Time, hours	Cooling
Sand Castings				
Annealing T21	341 to 346	645 to 655	2 to 4	Not critical
Precipitation T571[b]	168 to 174	335 to 345	40 to 48	Not critical
Solution heat treatment	518 to 524	965 to 975	6[a]	Still air
Precipitation T77[c] [d]	341 to 346	645 to 655	1 to 3	Not critical
Permanent Mold Castings				
Precipitation T571[b]	168 to 174	335 to 345	40 to 48	Not critical
Solution heat treatment	513 to 518	955 to 965	4[a]	Water at 150 to 212 F
Precipitation T61[c]	202 to 207	395 to 405	3 to 5	Not critical

(a) Soaking time periods required for average castings after load has reached specified temperature. Time can be decreased or may have to be increased, depending on experience with particular castings. (b) No solution heat treatment. (c) Start with solution heat treated material. (d) U. S. Patent 1,822,877.

Al – 4.5 Cu*

A 2 *Trade name.* 195 alloy (sand casting)
3 *ASTM number.* B 26-46T, Alloy C1
4 *Government number.* QQ-A-601, Class 4
B 1 *Typical uses.* Applications where a combination of high tensile properties, and good machinability are required. Flywheel housings, rear-axle housings, bus wheels, aircraft wheels, fittings and crankcases are typical.
C 1 *Density* at 20 C (68 F). 2.81 g per cu cm (0.101 lb per cu in.)
D 1 *Liquidus temperature.* 646 C (1195 F)
2 *Solidus temperature.* 549 C (1020 F)
6 *Thermal expansion*

20 to 100 C (68 to 212 F).	0.0000230 per °C
20 to 200 C (68 to 392 F).	0.0000240 per °C
20 to 300 C (68 to 572 F).	0.0000250 per °C

Conditions T4, T6, T62

11 *Specific heat* at 100 C (212 F). Approx 0.23 cal per g
13 *Latent heat of fusion.* Approx 93 cal per g
16 *Thermal conductivity* at 25 C (77 F). 0.33 cal/ sq cm/ cm/°C/sec, condition T4; 0.35 cal/sq cm/cm/°C/sec. condition T62
E 1 *Volume conductivity* referred to standard copper. 35%, condition T4; 37%, condition T62.
2 *Electrical resistivity* at 20 C (68 F). 4.926 microhm-cm, condition T4; 4.660 microhm-cm, condition T62.
11 *Electrolytic solution potential* versus N/10 calomel electrode is 0.70 volts, condition T4; 0.71 volts, condition T6; 0.73 volts, condition TC2 (53 g NaCl + 3 g H_2O_2 solution)
F 5 *Emissivity.* 0.035 to 0.07 at 25 C (77 F) in air
K *Mechanical Properties.* See Tables I and II. Modulus of elasticity 10,300,000 psi; modulus of rigidity 3,850,000 psi; Poisson's ratio 0.33.
L 2 *Radiography.* Same as for 85 alloy (Al – 5 Cu – 4 Si)
M *Composition Limits. Sand cast* (QQ-A-601, Class 4), *components:* 4.0 to 5.0% Cu; *impurities:* 1.00% max Fe; 1.20% max Si; 0.03% max Mg; 0.10% max Zn; 0.20% max Ti; others (total) 0.10% max.
2 *Consequences of exceeding impurity limits.* High iron or silicon decreases tensile properties, especially ductility. Manganese or magnesium decreases ductility. Tin reduces strength, hardness, and resistance to corrosion.
N 1 *Melting temperature.* 677 to 816 C (1250 to 1500 F)
2 *Casting temperature.* 677 to 788 C (1250 to 1450 F)
3 *Alloying.* Add copper as pure metal or aluminum-rich alloy to base metal (pure), either in melt-down or molten alloy.

Al – 3.8 Mg*

A *2 Trade name.* 214 alloy (sand casting)
3 ASTM number. B 26-46T, Alloy G1
4 Government number. QQ-A-601, Class 5
6 Foreign equivalents. British DTD 165

B *1 Typical uses.* Applications where excellent resistance to corrosion and tarnish are required. Dairy and food-handling equipment, cooking utensils, fittings for chemical and sewage use are typical.

C *1 Density* at 20 C (68 F). 2.65 g per cu cm (0.096 lb per cu in.)

D *1 Liquidus temperature.* 641 C (1185 F)
2 Solidus temperature. 579 C (1075 F)
6 Thermal expansion
20 to 100 C (68 to 212 F). 0.0000240 per °C
20 to 200 C (68 to 392 F). 0.0000250 per °C
20 to 300 C (68 to 572 F). 0.0000260 per °C
11 Specific heat at 100 C (212 F). Approx 0.23 cal per g
13 Latent heat of fusion. Approx 93 cal per g
16 Thermal conductivity at 25 C (77 F). 0.33 cal/sq cm/cm/°C/sec

E *1 Volume conductivity* referred to standard copper. 35%.
2 Electrical resistivity at 20 C (68 F). 4.926 microhm-cm
11 Electrolytic solution potential versus N/10 calomel electrode is 0.87 volts (53 g NaCl + 3 g H_2O_2 solution).

F *5 Emissivity.* 0.035 to 0.07 at 25 C (77 F) in air

K *Mechanical Properties. Sand cast:* Tensile strength 25,000 psi; yield strength 12,000 psi; compressive yield strength 12,000 psi; elongation (round specimens, ½-in. diam) 9.0%; Bhn (500-kg load, 10-mm ball) 50; modulus of elasticity 10,300,00 psi; shear strength 20,000 psi; endurance limit (based on 500,000,000 cycles using R. R. Moore type of rotating-beam machine) 5,500 psi; modulus of rigidity 3,850,000 psi; Poisson's ratio 0.33. See table at right.

Strength and Elongation at Elevated Temperatures
After prolonged heating at testing temperatures

Property	Temperature, deg Fahr				
	75 F	300 F	400 F	500 F	600 F
Tensile strength, psi	25,000	23,000	18,500	13,500	9,000
Yield strength, psi	12,000	15,000	12,500	8,000	4,000
Elongation, %	9	7	9	12	17

L *2 Radiography.* Same as for 13 alloy (Al – 12 Si)

M *Composition Limits. Sand cast* (QQ-A-601, Class 5), *components:* 3.2 to 4.3% Mg; *impurities* (*max*): 0.10% Cu, 0.60% Fe, 0.30% Si, 0.60% Mn, 0.10% Zn, 0.20% Ti, others (total) 0.10%.
2 Consequences of exceeding impurity limits. High copper or nickel greatly decreases resistance to corrosion and decreases ductility. High iron, silicon, or manganese decreases strength and ductility. Tin reduces resistance to corrosion.

N *1 Melting temperature.* 677 to 816 C (1250 to 1500 F)
2 Casting temperature. 677 to 788 C (1250 to 1450 F)
3 Alloying. Add magnesium as pure metal to molten base metal (pure).
5 Type of flux for remelting for casting. Gaseous, nitrogen or chlorine; or solid, aluminum chloride base.
17 Joining.

Rivet compositions. 53 S-T4, 53 S-T6, ■ S-T61. *Soft solder* with Alcoa No. 802; no flux. Rub-tin with Alcoa No. 802. *Braze* with Alcoa No. 717; Alcoa No. 33 flux; flame either reducing oxyacetylene or reducing oxyhydrogen. *Atomic-hydrogen weld* with 43 alloy; Alcoa No. 22 flux. *Oxyacetylene weld* with 43 alloy; Alcoa No. 22 flux; flame neutral. *Metal-arc weld* with 43 alloy; Alcoa No. 27 flux. *Carbon-arc weld* with 43 alloy; Alcoa No. 24 flux (automatic), Alcoa No. 27 flux (manual). *Tungsten-arc, argon atmosphere weld* with 43 alloy; no flux. *Resistance welding.* Spot, seam, and flash methods

Al – 3.8 Mg – 1.8 Zn*

A *2 Trade name.* A 214 alloy (permanent mold casting)

B *1 Typical uses.* Applications where good resistance to corrosion and tarnishing are required. Cooking utensils are the most typical application.

C *1 Density* at 20 C (68 F). 2.65 g per cu cm (0.096 lb per cu in.)

D *1 Liquidus temperature.* 638 C (1180 F)
2 Solidus temperature. 566 C (1050 F)
6 Thermal expansion
20 to 100 C (68 to 212 F). 0.0000240 per °C
20 to 200 C (68 to 392 F). 0.0000250 per °C
20 to 300 C (68 to 572 F). 0.0000260 per °C
11 Specific heat at 100 C (212 F). Approx 0.23 cal per g
13 Latent heat of fusion. Approx 93 cal per g
16 Thermal conductivity at 25 C (77 F). 0.31 cal/sq cm/cm/°C/sec

E *1 Volume conductivity* referred to standard copper. 33%
2 Electrical resistivity at 20 C (68 F). 5.225 microhm-cm

F *5 Emissivity.* 0.035 to 0.07 at 25 C (77 F) in air

K *Mechanical Properties. Permanent mold cast:* Tensile strength 27,000 psi; yield strength 16,000 psi; compressive yield strength 17,000 psi; elongation (round specimens, ½-in. diam) 7.0%; Bhn (500-kg load, 10-mm ball) 60; modulus of elasticity 10,300,000 psi; shear strength 22,000 psi; modulus of rigidity 3,850,000 psi; Poisson's ratio 0.33.

L *2 Radiography.* Same as for 13 alloy (Al – 12 Si)

M *Composition Limits. Permanent mold cast, components:* 3.5 to 4.3% Mg; 1.4 to 2.2% Zn; *impurities:* 0.10% max Cu; 0.30% max Si; 0.40% max Fe; 0.30% max Mn; others (each) 0.05% max.
2 Consequences of exceeding impurity limits. High copper, nickel, or tin impairs resistance to corrosion. High iron or silicon decreases strength and ductility. High silicon promotes hot cracking.

N *1 Melting temperature.* 677 to 816 C (1250 to 1500 F)
2 Casting temperature. 677 to 788 C (1250 to 1450 F)
3 Alloying. Add magnesium as pure metal to molten base metal (pure). Add zinc as pure metal to molten base metal (pure).
5 Type of flux for remelting for casting. Gaseous, nitrogen or chlorine; or solid, aluminum chloride base.
17 Joining. Rivet compositions. 53 S-T4, 53 S-T6, 53 S-T61. *Other joining methods.* Same as for 108 alloy (Al – 4 Cu – 3 Si).

Al – 8 Mg*

A *2 Trade name.* 218 alloy (die casting)
4 Government number. QQ-A-591, Class 7

B *1 Typical uses.* Applications where exceptional mechanical properties, resistance to corrosion and finishing characteristics are required.

C *1 Density* at 20 C (68 F). 2.53 ■ per cu cm (0.091 lb per cu in.)

D *1 Liquidus temperature.* 621 C (1150 F)
2 Solidus temperature. 541 C (1005 F)
11 Specific heat at 100 C (212 F). Approx 0.23 cal per g
13 Latent heat of fusion. Approx 93 cal per g
16 Thermal conductivity at 25 C (77 F). 0.24 cal/sq cm/cm/°C/sec

E *1 Volume conductivity* referred to standard copper. 24%.
2 Electrical resistivity at 20 C (68 F). 7.184 microhm-cm

F *5 Emissivity.* 0.035 to 0.07 at 25 C (77 F) in air

* Compiled by Aluminum Company of America

K *1 Mechanical Properties. Die cast*: Tensile strength 42,000 psi; yield strength 23,000 psi; elongation (round specimens, ¼-in. diam) 7.0%; modulus of elasticity 10,300,000 psi; endurance limit (based on 500,000,000 cycles using R. R. Moore type of rotating-beam machine) 18,000 psi; modulus of rigidity 3,850,000 psi; Poisson's ratio 0.33.

L *2 Radiography*. Type A or 506 film with no intensifying screen, cardboard exposure holder, 36-in. focal distance, General Electric OX-10 unit, 2.1 H&D film density.

Section, in.	Volts	Milliamperes	Time, min
½	60,000	9.0	1.0
1	90,000	6.0	1.0
1½	110,000	6.0	1.0
2	135,000	5.0	1.0

M *Composition Limits. Die cast.* (QQ-A-591, Class 7), *components:* 7.5 to 8.5% Mg; *impurities:* 1.8% max Fe; 0.20% max Cu; 0.30% max Si; 0.30% max Mn; 0.10% max Zn; 0.10% max Ni; 0.10% max Sn; others (total) 0.20% max.

2 Consequences of exceeding impurity limits. Relatively large quantities of impurities may be present before serious effects are detected. In general, increasing copper will lower resistance to corrosion and increasing iron will lower ductility.

N *1 Melting temperature*. 649 to 760 C (1200 to 1400 F)

2 Die-casting temperature. 635 to 704 C (1175 to 1300 F)

3 Alloying. Add magnesium as pure metal to molten base metal (pure).

5 Type of flux for remelting for casting. Gaseous, nitrogen or chlorine; or solid, aluminum chloride base.

17 Joining. Same as for 13 alloy (Al – 12 Si)

Al – 10 Mg*

A *2 Trade name*. 220 alloy (sand casting)

4 Government number. AN-A-33

B *1 Typical uses*. Applications where excellent machinability and resistance to corrosion with highest strength and elongation of any aluminum sand casting alloy are desired. Aircraft fittings, railroad passenger-car frames, miscellaneous castings requiring strength and shock resistance are typical.

C *1 Density* at 20 C (68 F). 2.58 ■ per cu cm (0.093 lb per cu in.)

D *1 Liquidus temperature*. 621 C (1150 F)

2 Solidus temperature. 499 C (840 F)

6 Thermal expansion
20 to 100 C (68 to 212 F). 0.0000245 per °C
20 to 200 C (68 to 392 F). 0.0000255 per °C
20 to 300 C (68 to 572 F). 0.0000265 per °C

11 Specific heat at 100 C (212 F). Approx 0.23 cal per ■

13 Latent heat of fusion. Approx 93 cal per g

16 Thermal conductivity at 25 C (77 F). 0.21 cal/sq cm/cm/°C/sec, condition T4

E *1 Volume conductivity* referred to standard copper. 21% condition T4

2 Electrical resistivity at 20 C (68 F). 8.210 microhm-cm, condition T4

11 Electrolytic solution potential versus N/10 calomel electrode is 0.89 volts, condition T4 (53 ■ NaCl + 3 g H_2O_2 solution)

F *5 Emissivity* 0.035 to 0.07 at 25 C (77 F) in air

K *Mechanical Properties. Sand cast, condition T4:* Tensile strength 46,000 psi; yield strength 25,000 psi; compressive yield strength 26,000 psi; elongation (round specimens, ½-in. diam) 14.0%; Bhn (500-kg load, 10-mm ball) 75; modulus of elasticity 10,300,000 psi; shear strength 33,000 psi; endurance limit (based on 500,000,000 cycles using R. R. Moore type of rotating-beam machine) 7,000 psi; modulus of rigidity 3,850,000 psi; Poisson's ratio 0.33.

Strength and Elongation at Elevated Temperatures

After prolonged heating at testing temperatures

Property	Temperature, deg Fahr				
	75 F	300 F	400 F	500 F	600 F
Tensile strength, psi	46,000	35,000	22,000	15,000	10,500
Yield strength, psi	25,000	19,000	11,500	7,500	3,500
Elongation, %	14	16	40	55	70

L *2 Radiography*. Same as for 218 alloy (Al – 8 Mg)

M *Composition Limits. Sand cast* (AN-A-33), *components:* 9.5 to 10.6% Mg; *impurities:* 0.20% max Cu; 0.30% max Fe; 0.20% max Si; 0.10% max Mn; 0.10% max Zn; others (each) 0.05% max; and others (total) 0.15% max.

2 Consequences of exceeding impurity limits. High copper or nickel greatly decreases resistance to corrosion. High iron, silicon or manganese decreases mechanical properties.

N *1 Melting temperature*. 677 to 816 C (1250 to 1500 F)

2 Casting temperature. 677 to 788 C (1250 to 1450 F)

3 Alloying. Add magnesium as pure metal to molten base metal (pure).

5 Type of flux for remelting for casting. Gaseous, nitrogen or chlorine; or solid, aluminum chloride base.

17 Joining.
Rivet compositions. 53 S-T4, 53 S-T6, 53 S-T61
Soft solder with Alcoa No. 802; no flux. Rub-tin with Alcoa No. 802.
Resistance welding. Spot, seam, and flash methods.

Al – 6 Si – 3.5 Cu*

A *2 Trade name*. 319 alloy (sand and permanent mold casting)

3 ASTM number. B 26-46T, alloy SC8 (sand); B 108-46T, alloy SC8 (permanent mold)

B *1 Typical uses*. Applications where good casting characteristics, good weldability, pressure tightness, and moderate strength are required. Automotive cylinder heads, internal combustion engine crankcases, typewriter frames and piano plates are typical.

C *1 Density* at 20 C (68 F). 2.77 g per cu cm (0.100 lb per cu in.)

D *1 Liquidus temperature*. 604 C (1120 F)

2 Solidus temperature. 510 C (950 F)

6 Thermal expansion
20 to 100 C (68 to 212 F). 0.0000215 per °C
20 to 200 C (68 to 392 F). 0.0000225 per °C
20 to 300 C (68 to 572 F). 0.0000235 per °C

11 Specific heat at 100 C (212 F). Approx 0.23 cal per g

13 Latent heat of fusion. Approx 93 cal per ■

16 Thermal conductivity at 25 C (77 F). 0.26 cal/sq cm/cm/°C/sec

E *1 Volume conductivity* referred to standard copper. 27%, sand; 28%, permanent mold

2 Electrical resistivity at 20 C (68 F).
6.386 microhm-cm, sand;
6.158 microhm-cm, permanent mold

11 Electrolytic solution potential versus N/10 calomel electrode is 0.81 volts, sand; 0.76 volts, permanent mold (53 ■ NaCl + 3 ■ H_2O_2 solution)

F *5 Emissivity*. 0.035 to 0.07 at 25 C (77 F) in air

K *Mechanical Properties*. See Table I. *Sand and permanent mold cast:* Modulus of elasticity 10,300,000 psi; modulus of rigidity 3,850,000 psi; Poisson's ratio 0.33.

L *2 Radiography*. Same as for 85 alloy (Al – 5 Si – 4 Cu)

* Compiled by Aluminum Company of America

Table I. Mechanical Properties of Al–6 Si–3.5 Cu

Condition	Tensile Strength,(a) psi	Yield Strength, psi	Elongation,(b) percentage	Brinell Hardness Number(c)	Shear Strength, psi	Endurance Limit,(d) psi	Compressive Yield Strength, psi
			Sand Cast				
As cast	27,000	18,000	2.0	70	24,000	10,000	18,000
T6	36,000	24,000	2.0	80	....	10,000	....
			Permanent Mold Cast				
As cast	34,000	19,000	2.5	85	24,000	....	19,000
T6	40,000	27,000	3.0	[illegible]	....	....	....

(a) In general, strengths and elongation are unchanged or improve at low temperatures.
(b) Round specimens, ½-in. diam.
(c) 500-kg load, 10-mm ball.
(d) Based on 500,000,000 cycles, using R. R. Moore type rotating-beam machine.

M *Composition Limits. Sand and permanent mold cast, components:* 2.5 to 4.5% Cu, 5.0 to 7.0% Si, *impurities (max):* 1.20% Fe, 0.50% Mg, 0.80% Mn, 1.00% Zn, 0.50% Ni, 0.20% Ti, others (total) 1.00%.

2 Consequences of exceeding impurity limits. High iron, manganese, nickel or magnesium decreases mechanical properties.

N *1 Melting temperature range.* 677 to 816 C (1250 to 1500 F)

2 Casting temperature. (sand) 677 to 788 C (1250 to 1450 F)

3 Alloying. Add silicon as pure metal or aluminum-rich alloy to base metal (pure), either in melt-down or molten alloy. Add copper as pure metal or aluminum-rich alloy to base metal (pure), either in melt-down or molten alloy.

5 Type of flux for remelting for casting. Gaseous type, nitrogen or chlorine; or solid, aluminum chloride base.

15 Heat Treatment.

Purpose	Temperature, deg Cent	Temperature, deg Fahr	Time, hours	Cooling
		Sand Castings		
Solution heat treatment ..	501 to 507	935 to 945	12(a)	Water at 150 to 212 F
Precipitation T6(b)	152 to 157	305 to 315	2 to 5	Not critical
		Permanent Mold Castings		
Solution heat treatment ...	501 to 507	935 to 945	8(a)	Water at 150 to 212 F
Precipitation T6(b)	152 to 157	305 to 315	2 to 5	Not critical

(a) Soaking time periods required for average castings after load has reached specified temperature. Time can be decreased or may have to be increased, depending on experience with particular castings.
(b) Start with solution heat treated material.

17 Joining. Same as for 108 alloy (Al–4 Cu–3 Si)

Al–5 Si–1.3 Cu–0.5 Mg*

A *2 Trade name.* 355 alloy (sand and permanent mold casting)

3 ASTM number. B 26-46T, Alloy SC21 (sand); B 108-46T, Alloy SC21 (permanent mold)

4 Government number. QQ-A-601, Class 10 (sand); QQ-A-596, Class 6 (permanent mold)

B *1 Typical uses.* Applications where good castability, weldability and pressure tightness are required. Aircraft supercharger covers, fuel-pump bodies, air-compressor pistons, liquid-cooled cylinder heads, liquid-cooled aircraft engine crankcases, water jackets, and blower housings are typical.

C *1 Density* at 20 C (68 F). 2.70 g per cu cm (0.098 lb per cu in.)

D *1 Liquidus temperature.* 627 C (1160 F)

2 Solidus temperature. 579 C (1075 F)

6 Thermal expansion.
20 to 100 C (68 to 212 F). 0.0000220 per °C
20 to 200 C (68 to 392 F). 0.0000230 per °C
20 to 300 C (68 to 572 F). 0.0000240 per °C

11 Specific heat at 100 C (212 F). Approx 0.23 cal per g

16 Thermal conductivity at 25 C (77 F).
0.40 cal/sq cm/cm/°C/sec, sand, condition T51
0.34 cal/sq cm/cm/°C/sec, sand, condition T6
0.35 cal/sq cm/cm/°C/sec, sand, condition T61
0.39 cal/sq cm/cm/°C/sec, sand, condition T7
0.36 cal/sq cm/cm/°C/sec, permanent mold, condition T6

E *1 Volume conductivity* referred to standard copper.
43%, sand, condition T51
36%, sand, condition T6
37%, sand, condition T61
42%, sand, condition T7
39%, permanent mold, condition T6

* Compiled by Aluminum Company of America

Table I. Mechanical Properties of Al–5 Si–1.3 Cu–0.5 Mg

Condition	Tensile Strength,(a) psi	Yield Strength, psi	Elongation,(b) percentage	Brinell Hardness Number,(c)	Shear Strength, psi	Endurance Limit,(d) psi	Compressive Yield Strength, psi
			Sand Cast

Table I. Mechanical Properties of Al–7 Si–0.3 Mg

Condition	Tensile Strength,[a] psi	Yield Strength, psi	Elongation,[b] percentage	Brinell Hardness Number[c]	Shear Strength, psi	Endurance Limit,[d] psi	Compressive Yield Strength, psi
Sand Cast							
T51	25,000	20,000	2.0	60	18,000	7,500	22,000
T6	33,000	24,000	4.0	70	27,000	8,000	22,000
T7	34,000	30,000	2.0	75	18,000	....	29,000
T71	28,000	21,000	4.5	60	16,000	....	.....
Permanent Mold Cast							
T6	40,000	27,000	5.0	90	.....	....	24,000
T7	33,000	.....	5.0	70	.....	....	.....

(a) In general, strengths and elongations remain unchanged or improve at low temperature.
(b) Round specimens, ½-in. diam
(c) 500-kg load, 10-mm ball
(d) Based on 500,000,000 cycles using R. R. Moore type of rotating-beam machine.

40%, sand, condition T7
41%, permanent mold, condition T6

2 Electrical resistivity at 20 C (68 F).
4.010 microhm-cm., sand, condition T51
4.421 microhm-cm., sand, condition T6
4.310 microhm-cm., sand, condition T7
4.205 microhm-cm., permanent mold, condition T6

11 Electrolytic solution potential versus N/10 calomel electrode is 0.82 volts, sand, condition T6 (53 g NaCl + 3 ▪ H_2O_2 solution)

F *5 Emissivity.* 0.035 to 0.07 at 25 C (77 F) in air

K *Mechanical Properties.* See Table I.
Modulus of elasticity 10,300,000 psi; modulus of rigidity 3,850,000 psi; Poisson's ratio 0.33.

Strength and Elongation at Elevated Temperatures
After prolonged heating at testing temperatures

Property	75 F	300 F	400 F	500 F	600 F
	Temperature, deg Fahr				
Sand Cast, Condition T6					
Tensile strength, psi	33,000	21,000	13,000	8,000	4,500
Yield strength, psi	24,000	16,000	9,000	5,500	3,000
Elongation, %	4	5	8	20	45

L *2 Radiography.* Same as for 13 alloy (Al–12 Si)

M *Composition Limits.* See Table II.
2 Consequences of exceeding impurity limits. High copper or nickel decreases ductility and resistance to corrosion. High iron decreases strength and ductility.

N *1 Melting temperature.* 677 to 816 C (1250 to 1500 F)
2 Casting temperature. (sand) 677 to 788 C (1250 to 1450 F); (permanent mold) 677 to 788 C (1250 to 1450 F)
3 Alloying. Add silicon as pure metal or aluminum-rich alloy to base metal (pure), either in melt-down or molten alloy. Add magnesium as pure metal to molten base metal (pure).
5 Type of flux for remelting for casting. Gaseous type, nitrogen or chlorine; or solid type, aluminum chloride base.

15 Heat treatment.

Purpose	Temperature, deg Cent	Temperature, deg Fahr	Time, hours	Cooling
Sand Castings				
Precipitation T51[c]	224 to 230	435 to 445	7 to 9	Not critical
Solution heat treatment	535 to 541	995 to 1005	12[a]	Water at 150 to 212 F
Precipitation T6[d]	152 to 158	305 to 315	2 to 5	Not critical
Precipitation T7[b][d]	224 to 230	435 to 445	7 to 9	Not critical
Precipitation T71[d]	243 to 249	470 to 480	2 to 4	Not critical
Permanent Mold Castings				
Solution heat treatment	535 to 541	995 to 1005	8[a]	Water at 150 to 212 F
Precipitation T6[d]	152 to 157	305 to 315	3 to 5	Not critical
Precipitation T7[b][d]	224 to 230	435 to 445	7 to 9	Not critical

(a) Soaking time periods required for average casting after load has reached specified temperature. Time can be decreased or may have to be increased, depending on experience with particular castings.
(b) U. S. Patent No. 1,822,877
(c) No solution heat treatment.
(d) Start with solution heat treated material.

17 Joining. Same as for 214 alloy (Al–3.8 Mg)

Table II. Composition Limits of Al–7 Si–0.3 Mg

Form	Designation	Components: Si min	Si max	Mg min	Mg max	Impurities: Cu max	Fe max	Mn max	Zn max	Ti max	Others total max
Sand cast	QQ-A-601, Class 3	6.5	7.5	0.20	0.40	0.20	0.60	0.10	0.10	0.20	0.10
Permanent mold cast	QQ-A-596, Class 8	6.5	7.5	0.20	0.40	0.20	0.60	0.10	0.10	0.20	0.10

Al – 8 Si – 1.5 Cu – 0.3 Mg – 0.3 Mn

COMPILED BY F. ROMANO*

A *2 Trade name.* Red X-8 (sand and permanent mold casting)
3 ASTM number. B 26–46T, Alloy SC 42 (sand); B 108–46T, Alloy SC 42 (permanent mold).
4 Government number. 46 A 15 (Interim)

B *1 Typical uses.* A general-purpose aluminum alloy for sand and permanent mold castings, which has its properties improved by solution heat treatment. It is used in castings for internal combustion engines or other machine parts subjected to high stresses at elevated temperatures.
2 Precautions in use. Because this alloy contains 8% Si, it is subject to about 0.001 in. per in. growth if heated to approximately 400 F in use or fabrication. A heat treatment of 5 hr at 450 F applied to rough castings will prevent further dimensional change from this cause.

C *1 Density* at 20 C (68 F). 2.73 g per cu cm (0.099 lb per cu in.)

D *6 Thermal expansion* 20 to 100 C (68 to 212 F). 0.0000214 per °C
16 Thermal conductivity at 20 C (68 F). 0.24 cal/sq cm/cm/°C/sec, as cast; 0.27 cal/sq cm/cm/°C/sec, stress relieved

E *1 Volume conductivity* referred to standard copper. 26%, as cast; 29%, stress relieved

K *Mechanical Properties.* See Tables I and II.

M *Composition Limits. Sand and chill cast, components:* 1.0 to 2.0% Cu; 0.20 to 0.60% Mg; 0.20 to 0.60% Mn; 7.0 to 8.6% Si; 0.3% max Ti; *impurities:* 1.0% max Fe; 0.2% max Ni; 0.5% max Zn; 0.3% max Cr; others (total) 0.5% max.

* Research Laboratory, National Smelting Company, Cleveland.

Table I. Mechanical Properties of Al – 8 Si – 1.5 Cu – 0.3 Mg – 0.3 Mn

Condition	Tensile Strength, psi	Yield Strength,[a] psi	Elongation,[b] percentage	Rockwell E Hardness

(a) Round specimen, ½-in. diam

N 6 *Precautions in melting:* If the metal is heated to more than 1375 F some pinhole porosity may result. For the production of castings free from pinhole porosity, made with pouring temperatures over 1375 F, the melt should be degassed with chlorine, nitrogen, or boron trichloride. Loss of magnesium should be controlled.

Al – 9.5 Si – 0.5 Mg*

A 2 *Trade name.* 360 alloy (die casting)
5 *Other designations.* SAE AMS 4290
B 1 *Typical uses.* Applications where excellent castability and resistance to corrosion are required. Miscellaneous thin-walled and intricate castings are typical.
C 1 *Density* at 20 C (68 F). 2.68 g per cu cm (0.097 lb per cu in.)
D 1 *Liquidus temperature.* 591 C (1095 F)
2 *Solidus temperature.* 566 C (1050 F)
6 *Thermal expansion*
20 to 100 C (68 to 212 F). 0.0000195 per °C
20 to 200 C (68 to 392 F). 0.0000205 per °C
20 to 300 C (68 to 572 F). 0.0000215 per °C
11 *Specific heat* at 100 C (212 F). Approx 0.23 cal per g
13 *Latent heat of fusion.* Approx 93 cal per g
16 *Thermal conductivity* at 25 C (77 F). 0.35 cgs
E 1 *Volume conductivity* referred to standard copper. 37%
2 *Electrical resistivity* at 20 C (68 F). 4.660 microhm-cm
F 5 *Emissivity.* 0.035 to 0.07 at 25 C (77 F) in air
K *Mechanical Properties. Die cast:* Tensile strength 42,000 psi; yield strength 23,000 psi; elongation (round specimens, ¼-in. diam) 1.8%; modulus of elasticity 10,300,000 psi; modulus of rigidity 3,850,000 psi; Poisson's ratio 0.33.
L 2 *Radiography.* Same as for 355 alloy (Al – 5 Si – 1.3 Cu – 0.5 Mg)
M *Composition Limits. Die cast* (AMS 4290), *components:* 9.0 to 10.0% Si; 0.40 to 0.60% Mg; *impurities:* 2.0% max Fe; 0.60% max Cu; 0.30% max Mn; 0.50% max Zn; 0.50% max Ni; 0.10% max Sn; others (total) 0.20% max.
2 *Consequences of exceeding impurity limits.* Relatively large quantities of impurities may be present before serious effects are detected. In general, increasing copper will lower resistance to corrosion and increasing iron will lower ductility.
N 1 *Melting temperature range.* 649 to 760 C (1200 to 1400 F)
2 *Die-casting temperature range.* 635 to 704 C (1175 to 1300 F)
3 *Alloying.* Add silicon as pure metal or aluminum-rich alloy to base metal (pure), either in melt-down or molten alloy. Add magnesium as pure metal to molten base metal (pure).
5 *Type of flux* for remelting for casting. Gaseous type, nitrogen or chlorine; or solid type, aluminum chloride base.
17 *Joining.* Same as for 13 alloy (Al – 12 Si)

Al – 8.5 Si – 3.5 Cu*

A 2 *Trade name.* 380 alloy, 4–9 alloy (die casting)
3 *ASTM number.* B 85–46T, Alloy SC7
4 *Government number.* QQ–A–591, Class 11.
B 1 *Typical uses.* General-purpose applications where greater castability is required than that afforded by 85 alloy (Al – 5 Si – 4 Cu).
C 1 *Density* at 20 C (68 F). 2.76 g per cu cm (0.099 lb per cu in.)
D 1 *Liquidus temperature.* 588 C (1090 F)
2 *Solidus temperature.* 521 C (970 F)
11 *Specific heat* at 100 C (212 F). Approx 0.23 cal per g
13 *Latent heat of fusion.* Approx 93 cal per g
16 *Thermal conductivity* at 25 C (77 F). 0.26 cal/sq cm/cm/°C/sec
E 1 *Volume conductivity* referred to standard copper. 27%
2 *Electrical resistivity* at 20 C (68 F). 6.386 microhm-cm
F 5 *Emissivity.* 0.035 to 0.07 at 25 C (77 F) in air
K *Mechanical Properties. Die cast:* Tensile strength 45,000 psi; yield strength 25,000 psi; elongation (round specimens, ¼-in. diam) 2.0%; modulus of elasticity 10,300,000 psi; modulus of rigidity 3,850,000 psi; Poisson's ratio 0.33.
L 2 *Radiography.* Same as for 85 alloy (Al – 5 Cu – 4 Si)
M *Composition Limits. Die cast* (QQ–A–591, Class 11), *components:* 7.5 to 9.5% Si; 3.0 to 4.0% Cu; *impurities:* 2.0% max Fe; 0.10% max Mg; 0.50% max Mn; 1.0% max Zn; 0.50% max Ni; others (each) 0.15% max, and others (total) 0.50% max.
2 *Consequences of exceeding impurity limits.* Relatively large quantities of impurities may be present before serious effects are detected. In general, increasing iron will lower ductility.
N 1 *Melting temperature.* 649 to 760 C (1200 to 1400 F)

* Compiled by Aluminum Company of America

2 *Die-casting temperature range.* 635 to 704 C (1175 to 1300 F)
3 *Alloying.* Add copper as pure metal or aluminum-rich alloy to base metal (pure), either in melt-down or molten alloy. Add silicon as pure metal or aluminum-rich alloy to base metal (pure), either in melt-down or molten alloy.
5 *Type of flux* for remelting for casting. Gaseous, nitrogen or chlorine; or solid, aluminum chloride base
17 *Joining.* Same as for 13 alloy (Al – 12 Si)

Al – 6.5 Sn – 1 Cu – 1 Ni*

A 2 *Trade name.* 750 alloy (permanent mold casting)
B 1 *Typical uses.* Applications where excellent bearing qualities are required. Bearings and bushings.
C 1 *Density* at 20 C (68 F). 2.89 g per cu cm (0.104 lb per cu in.)
D 1 *Liquidus temperature.* 649 C (1200 F)
2 *Solidus temperature.* 232 C (450 F)
6 *Thermal expansion*
20 to 100 C (68 to 212 F). 0.0000231 per °C
20 to 200 C (68 to 392 F). 0.0000243 per °C
11 *Specific heat* at 100 C (212 F). Approx 0.23 cal per ■
13 *Latent heat of fusion.* Approx 93 per g
16 *Thermal conductivity* at 25 C (77 F). 0.42 cal/sq cm/cm/°C/sec
E 1 *Volume conductivity* referred to standard copper. 45%
2 *Electrical resistivity* at 20 C (68 F). 3.831 microhm-cm
F 5 *Emissivity.* 0.035 to 0.07 at 25 C (77 F) in air
K *Mechanical Properties. Permanent mold cast, condition T5:* Tensile strength 22,000 psi; yield strength 10,000 psi; compressive yield strength 10,000 psi; elongation (round specimens, ½-in. diam) 12%; Bhn (500-kg load, 10-mm ball) 45; modulus of elasticity 10,300,000 psi; shear strength 14,000 psi; endurance limit (based on 500,000,000 cycles using R. R. Moore type of rotating-beam machine) 9000 psi; modulus of rigidity 3,850,000 psi; Poisson's ratio 0.33.

* Compiled by Aluminum Company of America

L 2 *Radiography.* Type A or 506 film with no intensifying screen, cardboard exposure holder, 36-in. focal distance, General Electric OX-250 unit, 2.1 H&D film density.

Section, in.	Volts	Milliamperes	Time, min
½	140,000	5.0	1.0
1	180,000	5.0	1.0
1½	185,000	7.0	1.0
2	200,000	10.0	1.0

M *Composition Limits. Permanent mold cast, components:* 5.5 to 7.0% Sn; 0.70 to 1.3% Cu; 0.70 to 1.3% Ni; *impurities:* 0.70% max Si; 0.70% max Fe; 0.10% max Mn; 0.20% max Ti; others (total) 0.30% max.
2 *Consequences of exceeding impurity limits.* High iron, manganese, or magnesium decreases ductility and increases hardness. High silicon modifies bearing characteristics.
N 1 *Melting temperature.* 649 to 732 C (1200 to 1350 F)
2 *Casting temperature.* 649 to 704 C (1200 to 1300 F)
3 *Alloying.* Add tin as pure metal to molten base metal (pure). Add copper as pure metal or aluminum-rich alloy to base metal (pure), either in melt-down or molten alloy. Add nickel as aluminum-rich alloy to melt-down or molten base metal (pure).
5 *Type of flux* for remelting for casting. Gaseous type, nitrogen or chlorine; or solid type, aluminum chloride base.

Al – 5.5 Zn – 0.6 Mg – 0.5 Cr – 0.2 Ti*

A 2 *Trade name.* 40 E alloy (sand casting)
3 *ASTM number.* B 26–46T, Alloy ZG41
4 *Government number.* AN-A-17; 46A1 (Int), Class 1
5 *Other designations.* SAE 310, AFA B 81
B 1 *Typical uses.* Applications where a good combination of mechanical properties is required without heat treatment: shock and corrosion resistance, machinability, dimensional stability, and freedom from distortion caused by heat treatment. Airplane stressed parts, turret housings, air-compressor pistons, instrument parts, and machine parts subjected to shock.
C 1 *Density* at 20 C (68 F). 2.81 g per cu cm (0.101 lb per cu in.)
D 1 *Liquidus temperature.* 760 C (1140 F)
2 *Solidus temperature.* 572 C (1060 F)
6 *Thermal expansion* 21 to 93 C. 0.0000247 per °C
11 *Specific heat* at 100 C (212 F). Approx 0.23 cal per ■
13 *Latent heat of fusion.* Approx 93 cal per g
16 *Thermal conductivity* at 25 C (77 F). 0.33 cgs
E 1 *Volume conductivity* referred to standard copper. 35%
2 *Electrical resistivity* at 20 C (68 F). 4.926 microhm-cm
F 5 *Emissivity.* 0.035 to 0.07 at 25 C (77 F) in air
K *Mechanical Properties. Sand cast*: Tensile strength 35,000 psi; yield strength 25,000 psi; elongation (round specimens, ½-in. diam) 5%; Bhn (500-kg load, 10-mm ball) 80; modulus of elasticity 10,300,000 psi; impact value (Charpy) 2 to 3 ft-lb; shear strength 27,800 psi; endurance limit (based on 500,000,000 cycles using R. R. Moore type of rotating-beam machine) 9,000 psi; Poisson's ratio 0.33; compressive proportional limit 14,000 psi; low-temperature strength after 24 hr at minus 94 F, tensile strength 38,400 psi and elongation 5%. See table at right.

* Compiled by Frontier Bronze Corporation

Strength and Elongation at Elevated Temperatures
After 1000 hr at testing temperature

Property	Temperature, deg Fahr: 175 F	250 F	350 F
Tensile strength, psi	33,800	29,500	19,700
Yield strength, psi	30,700	25,200	17,000
Elongation, %	3	2	6

L 2 *Radiography.* Same as for 113 alloy (Al – 7 Cu – 2 Si – 1.7 Zn)
M *Composition Limits. Sand cast* (ASTM B 26–46T, Alloy ZG41), *components*: 5.0 to 6.0% Zn; 0.50 to 0.65% Mg; 0.40 to 0.60% Cr; 0.10 to 0.30 Ti; *impurities,* 0.30% max Cu; 1.00% max Fe; 0.25% max Si; 0.30% max Mn; others (each) 0.05% max.
N 1 *Melting temperature range.* 677 to 802 C (1250 to 1475 F)
2 *Casting temperature range.* 677 to 802 C (1250 to 1475 F)
3 *Alloying.* Add magnesium as pure metal to base metal (pure) to compensate for furnace loss.
5 *Type of flux* for remelting for casting. Gaseous type, nitrogen or chlorine; or solid type, sodium chloride-sodium fluoride base.
15 *Heat treatment.* Precipitation, at 180 C (356 F), 10 hr; cooling not critical. An optional 21-day aging at room temperature may be substituted.
17 *Joining.*
Soft solder with Alcoa No. 802; no flux. Rub-tin with Alcoa No. 802.
Braze with Alcoa No. 717; Alcoa No. 33 flux in furnace atmosphere.
Oxyacetylene weld with 40 E alloy; Alcoa No. 22 flux; flame neutral.
Resistance welding. Spot, seam, and flash methods

The Copper Industry

By T. E. Veltfort*

COPPER and copper alloys pass through so many processes from mine to consumer that no adequate review of the copper industry is possible without at least a cursory study of the sequence of processes. To permit such a study, Fig. 1 is presented.

Statistics on copper and copper products at various stages included in Fig. 1, are assembled by several organizations in varying degrees of detail and from divers viewpoints. No effective attempt to reconcile and co-ordinate

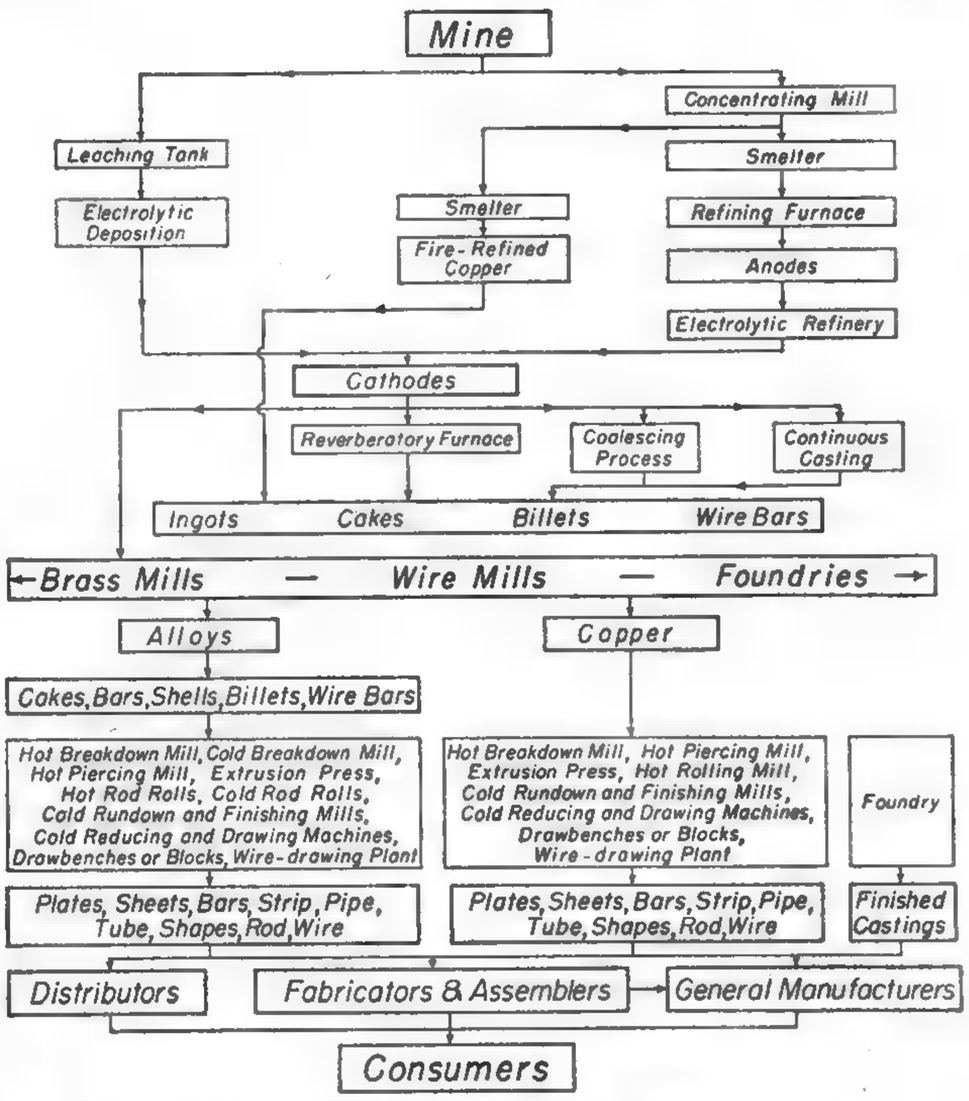

Fig. 1 Flow chart showing copper from mine to consumer

such statistics has been practicable so far and, accordingly, the use of available statistics requires an appreciation of their limitations. Accuracy is not in question since most statistics of this kind are essentially accurate at the level and source compiled. The important need is for interpretation and reliable use of these available data for comparative purposes. Copper statistics in the United States are collected principally by the American Bureau of Metal Statistics, by the U. S. Bureau of Mines, by the Copper Institute and the U. S. Copper Association. Each of these authoritative bodies covers somewhat different areas, a circumstance that leads to differences in their findings; but even where the areas overlap there are differences. Basic data are the same, for they must come from the same mines, smelters and refiners. Each authority, however, has its own questionnaire or report form, which differs from the others and, therefore, produces answers that also differ.

The situation is further complicated by the effect of stocks at various levels of use. To illustrate this, advantage may be taken of the results of a study made by the War Production Board concerning the flow of copper in a representative month in 1943. Figure 2 presents this information in simplified form. It will be noted that at every point of use, copper flows into stocks, and because these stocks form a reserve that is constantly increasing or diminishing, the inflow of copper for any short period of time is likely to differ from the outflow of copper content in processed material. Statistics will differ, therefore, depending on whether they represent the copper content of the raw material in process, the copper content of material actually processed, or the copper content of the material actually delivered to the next process. Aside from the necessity of making allowance for these factors, there is the difference of opinion among the reporting organizations as to what constitutes stocks. Thus, for example, in reporting stocks of copper actually on hand at refineries, one authority treats cathodes (which are refined copper and, as shown in Fig. 1, may be delivered in that form for consumption) as refined stock; another treats them as stock "in process", because, as also shown in Fig. 1, cathodes may pass through a melting furnace to be cast into wire bars, cakes, ingots or other shapes.

Imports and exports also create statistical difficulties. During normal times considerable copper in various forms reaches this country from abroad to be processed in bond and then returned. Statistics of imports and exports must make appropriate allowance for such material. A difference in the classification of exports, moreover, arises from the fact that some statisticians classify copper rod, of which a substantial quantity is exported, as a primary product, and include it in wire bars because much of it is used for drawing into wire. Others consider copper rod a manufactured product, rod.

Secondary copper occasions a particularly confusing disagreement. Statistical treatment of this metal differs among authorities and there is no accepted definition of what secondary copper is. One authority holds that the only true secondary copper is that reclaimed from industrial use, excluding all turnings, borings and other processing

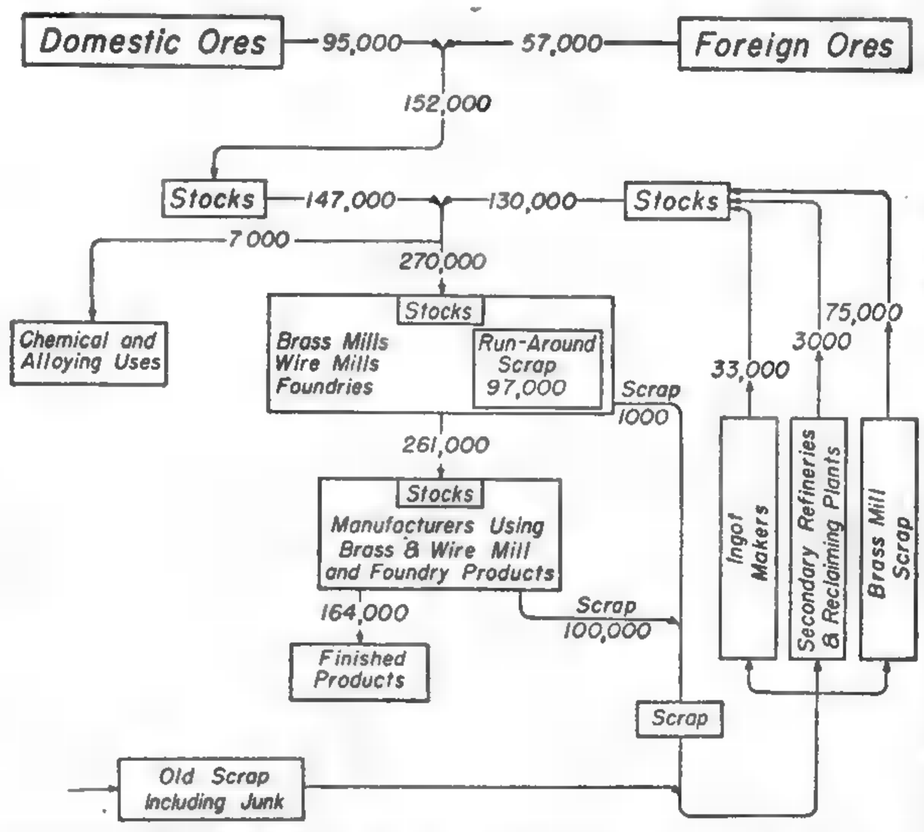

Fig. 2 Course of copper from origin through fabrication and reuse for a representative month in 1943. (Quantities represent copper content in short tons.)

scrap, which he considers run-around copper. There is sound logic for this viewpoint, as indicated in Fig. 2. It will be noted that in the brass mills, wire mills and foundries, a considerable quantity of copper is designated as "run-around", consisting of gates, croppings, ends, and process scrap, which in normal operations never leaves the plants. Also, a minor quantity of unusable scrap is shown leaving the mills, and a much more substantial quantity of scrap, such as turnings, borings, and skeleton scrap, is shown leaving the fabricating plants. However, the major part of this material returns to the mills as scrap or is processed immediately into ingots and other forms for use by the mills and foundries. In that sense, such scrap may be considered an extension of the mills' own run-around. Other statisticians, however, do not adopt this view. This was a factor of particular importance during World War II because of the high proportion of

* Manager, Copper & Brass Research Association, New York

scrap resulting from the manufacture of cartridge cases from brass disks.

The sources of the following statistics have been selected with a view to affording consistent and comparable data derived on a basis that should make them significant for the anticipated users of this section of the Handbook. Because of the situation outlined above, it has appeared needless to show production and related data in units smaller than thousands of tons of 2000 lb each.

In the following tabulation, the available statistics for the period from 1928 to 1945 have been organized and presented thus:

Table I. Production of Copper on the Basis of Origin of Ore. This represents copper as mined, and is a convenient and significant series for over-all information on world and domestic mine production and the relation of the two.

Table II. Production of Refined Copper Regardless of Origin of Ore. This indicates the actual refining activity in this country. Normally, half again as much copper is refined in the U. S. as is mined here. It will be noted, by comparison with Table I, that during some years the copper refined in the U. S. has been about twice the volume mined domestically, though that proportion appears to be abnormal.

Table III. Production of Refined Copper in U. S. Comparison of Data. This presents first, parts (*a*) and (*b*), volume of copper refined, as compiled from the American Bureau of Metal Statistics and the Bureau of Mines data, respectively. The results on lines 13 and 16 are in substantial agreement, for ordinary comparisons.

As a second approach, this table in parts (*c*) and (*d*), presents comparable data as given by the Copper Institute and as compiled from the figures of the American Bureau of Metal Statistics, respectively. These data, however, are limited to copper refined by primary refiners from domestic ore and from secondary copper. Here again the agreement is fairly close (*compare* lines 17 and 20).

Table IV. New and Old Copper Used in U. S. This table presents information as compiled (*a*) from data of the American Bureau of Metal Statistics and (*b*) from data of the Bureau of Mines. In general, the first series is on a mine production basis, the second on a refinery basis. Considering the difference in approach for these two series, it is significant that the totals (lines 30 and 41) for most of the years covered, are in reasonable agreement. This table, in lines 31 and 42, also shows the percentage of copper used that has been derived from old scrap.

Tables I to IV. Significant Copper Statistics (1928 to 1945)
